The subject of bridge accommodation in Newcastle has been much mooted lately in public meetings, and otherwise it is one that immediately affects practitioners here who cannot, without much loss of time, pass over to Byker, a district of the borough containing a population of 30,000, without paying toll going and returning. A bridge over a ravine of the Ouseburn was constructed by a private company; the people now reasonably ask for the purchase of the bridge by the Corporation, seeing that they contribute so largely to the rates, and are likely to do more so in the future provided the bridge is made free. Newcastle and Gateshead, so far as regards medical practice, may be considered one town, for Newcastle men visit a good deal in Gateshead, and our Gateshead neighbours return the compliment, perhaps with "interest," yet there is no practical way of passing between the towns, without much loss of time and some risk from dangers of heavy traffic, except by taking choice of two bridge tolls. It is not too much to hope that the inhabitants of both great towns may bestir themselves before long, and ask for freedom of communication. But would you believe it? There is actually a medieval impost also kept up, by which small articles of merchandise and food are taxed by the Corporation of Newcastle. This relic of "the dark ages" is called "the through toll;" and to see a poor man's cart stopped, and the traffic thereby impeded while the search goes on, makes a stranger doubt his whereabouts, the impost and custom so much resemble the *octroi* of continental towns.

The photographic art has attractions for some of our practitioners as a useful amusement, as was evidenced by the meeting of the Newcastle and Northern Counties' Photographic Society held here the other day, Dr. G. Berwick of Sunderland presiding. Dr. G. Berwick has himself followed the art as an amateur with not a little success, and has made it subservient in portraying forms of parasitic disease. I saw a very nice picture by him, which was developed two years after exposure; the character of the work spoke well in the durability of effects for the care exercised by the operator.

It may interest those of your readers who are chess-players to know that we are having a visit from Mr. J. H. Blackburne, the great player; and on Friday last he played eight simultaneous games blindfolded, in which he was pitted against some of our crack players, with the result of winning five, two were drawn, and he lost only one. Was not this a physiological as well as an intellectual feat, as during the battle, which lasted several hours, he sustained himself solely by a cup of coffee and an occasional havannah?

Newcastle-on-Tyne, Nov. 28th, 1882.

## SCOTTISH NOTES.

(From our own Correspondent.)

I HAVE so recently had something to say regarding the position occupied by Professor Pirrie, at Aberdeen, that I do not now wish to say more than his loss, had it come before his day's work was well done, would have been quite irretrievable. His whole soul was engaged in his work as a teacher; and old students everywhere will feel his death as a great personal grief.

So far as yet ascertained, the number of matriculated students of medicine at Aberdeen University for the present winter session is 314, an advance of 23 upon last year's aggregate.

Interest attaches to the report of Mr. Turnbull, M.B., superintendent of the Fife Asylum, chiefly from the enthusiasm with which he, aided largely by Dr. Fraser, Deputy Commissioner in Lunacy, carried out the system of boarding out his chronic cases. Year by year there is a stronger tendency on the part of superintendents to adopt this

method of relief from overcrowding, but it too often seems that it is only because the house will hold no more that these harmless creatures are sent into the suitable quiet of the cotter's family. If the commissioners' reports are looked into, it will be found that there are some asylums where the boarding-out system has certainly been put into force, but it is evident that the patients have been squeezed out only to make room for more urgent cases. Mr. Turnbull evidently pursues the subject *con amore*. Taking all the reasons for the discharge of patients, he shows that the admissions will usually exceed the number discharged by about 20 per cent.; and he argues that this residuum might in great part be suitably consigned to the care of people of the same class as that to which the patients themselves belong; that they can thus be most economically supported; that they there lead happier, and often useful, lives; and that, in point of fact, his own experience, and that of his predecessors, show the advantages of the plan. He finds no difficulty in securing suitable guardianship; though he apparently sends the greater number of his cases at first on probation, he finds that few require readmission. During the five months ending in July, twenty-five cases were disposed of in this way; and the general result for the year is, that notwithstanding an admission rate above the average, the number of patients under treatment is eighteen less than at the end of last year.

The General Board of Commissioners in Lunacy has just been successful in an action of considerable importance to those engaged in the working of the lunacy laws. The Board craved power for the removal of a female lunatic from her mother's charge, and that she might be placed in the asylum. The application was under section 14 of the Act 29 and 30 Vic., chap. 51, and evidence showed that the patient was subjected to compulsory confinement in her mother's house, and that the filthy manner in which she was kept amounted to harsh or cruel treatment. The authorities of the parish of Cameron concurred in the application, and the sheriff granted a warrant for the removal of the lunatic.

From the appointments made last week at the University College, Dundee, it appears that considerable caution is being exercised before the authorities commit themselves to any scheme for the general teaching of science. The appointments now made complete what will form the first teaching staff, but so far only five chairs have been filled—viz., classics, mathematics, chemistry, English, and engineering. These are all classes which must necessarily be provided in such a college as is proposed for Dundee; but the profession will be chiefly interested in knowing what is to be done with the other science subjects which form part of the medical curriculum. The chief difficulty exists in finding a simple and satisfactory agreement between St. Andrews and the new institution, by which the new and well-endowed school should have recognition and status accorded it by its dignified and ancient neighbour, while the latter might have that association with a large commercial centre, which seems, now-a-days, so needful to success. With the new Tay Bridge, Dundee will be but half an hour distant from St. Andrews, and in such close proximity two strong colleges can scarcely exist in rivalry. The newly appointed professors are young, and apparently able men in their respective departments.

### PARIS.

(From our Paris Correspondent.)

At the last meeting of the Academy of Sciences M. M. Charles Richet and Rondeau submitted a short note on some experiments performed by them, with a view of studying the mechanism of death by the action of extreme cold. Dogs resisted extremely low temperatures without any inconvenience, whereas rabbits submitted to the same temperature were with great difficulty restored to their normal condition. These animals, subjected gradually to temperatures marked by the Centigrade thermometer 20° C., 18° C., 15° C., 14° C., below freezing point, or within four degrees of 0° F., presented the following phenomena: The respiration was slackened, the excitability of the muscular system was gradually diminished, although it lasted for some time, the contractions of the fibres continued, but slowly as in chelonian reptiles,

the turtle, for instance. The pulse was reduced in the number of beats. At a temperature of 17° C. below freezing-point only ten or twelve beats per minute could be counted. The authors assert that animals suffering under the influence of extreme cold, and in which their vital energy would be insufficient if left to themselves may be restored to their normal condition by artificial respiration; and they add that a sort of artificial hibernation may be produced in animals, provided the refrigeration does not exceed certain limits.

At the same meeting, M. Béchamp read a paper relating to the influence of hydrocyanic acid on oxygenated water by fibrine. The result of the experiments performed by the learned professor was that the acid, so powerfully toxic, is destroyed by contact with fibrine.

M. Faye, the Director of the Paris Observatory, has endeavoured to explain the cause of the almost incessant fall of rain we have had during the present year, and which has been more or less prevalent all over the continent of Europe. According to the learned astronomer the number of comets that have made their appearance within the last four years would be the only cause of this atmospheric perturbation. These wandering stars, which move around the sun, absorb a very great proportion of its rays. The heat not being sufficient to draw up the vapours accumulated around our planet, the result is the condensation of these vapours, which fall to the earth in the form of continual rain. If the comets continue during a certain number of years to obstruct the sun's rays, M. Faye predicts the earth will become unproductive, and be transformed into an extinct globe, floating about in the air in obedience to the laws of gravitation. I may, however, observe that the cause of unusually dry seasons has been attributed also to the presence of comets.

Dr. Martineau, physician to the Lourcine Hospital, delivered a series of interesting lectures on "The Evolution of Syphilis." He devoted a whole lecture to the medical geography of that malady, of which I send a short summary. He commenced his lecture by observing that the subject under notice was very interesting, but at the same time most difficult to solve. He then put the question, Why should the evolution of syphilis take place abnormally? What are the etiological factors of this deviation of the evolution of this malady? In his inaugural thesis Dr. Ott, one of Dr. Martineau's pupils, has attempted to solve the questions, and he has studied the various circumstances which would appear to exercise a certain influence on the evolution of syphilis. The author remarks that military and naval surgeons have written a great deal on the subject, but they have fixed their attention only on the influence of climate in the evolution of the malady, without taking into consideration other factors. All writers, however, on the subject seem to be agreed on one point—viz., that the temperature alone does not appear to influence, in a marked degree, the evolution of syphilis. But if only the temperature be taken into account, syphilis would show itself in a more aggravated form in the temperate and warm zones than in the tropical, torrid, or the polar regions. Dr. Ott, however, observes that the gravity of the malady depends less on the climate than on defective hygiene, and on the existence of any previous malady (scrofula, tuberculosis), or on endemic cachexia (paludism, alcoholism).

A telegram has been received in Paris contradicting the report of the persistence of cholera at Mecca, whereas the Egyptian delegate at Alexandria declared that the disease is still prevailing at that place. The French Minister of Commerce, however, not placing much reliance on these contradictory reports, has taken such measures as will prevent the incursion of the malady into Europe, and among others he has stationed at the Italian opening of the tunnel at Mont-Cenis, two chemists who are charged with the duty of submitting all letters and other papers coming from the East *via* Brindisi and the Italian railways to a particular process of disinfection before being transmitted to their destination.

An epidemic of typhoid fever has broken out at Saintes, a small town in the department of the Lower Charente. There have been upwards of 200 cases during the last week, which is considered a large proportion, as the inhabitants number only about 12,000. Several of the nuns who have been attending the sick have fallen victims to the malady.

The epidemic of Paris continues to decline, and hopes are entertained that it will soon disappear altogether. The present epidemic has been productive of some good, it has aroused the municipal authorities to a

of the importance of attending to sanitary measures, the treatment of the malady is being fully discussed at the Academy of Medicine. is, Nov. 28th, 1882.

## MEDICAL NOTES IN PARLIAMENT.

### *Scurvy in the Mercantile Marine.*

At the House of Commons on Monday, Mr. Dillwyn asked whether the President of the Board of Trade was prepared to take any action upon the report of Mr. Thomas Gray as to the increase of scurvy in the mercantile marine.—Mr. John Holms replied that the report had been forwarded to various local marine boards, with a circular asking for their observations. Some of the replies had not yet been received, the matter was under consideration, and it was at present impossible to say what action the Board of Trade would decide to take.

### *Brixton Military Prison.*

Sir A. Hayter, in reply to Mr. Bourke, said Sir Edmund Cane, Surveyor-General of Prisons, had received no report of any injury to the mental or physical condition of prisoners by the system of solitary confinement at Brixton Military Prison. The prisoners were mainly employed in rum-picking, and were kept in their cells except when at drill, exercise, or shot drill. He would communicate with the army clothing department, and see whether some employment other than rum-picking could not be found for those who were eligible for it.

### *Vaccination Questions.*

On Tuesday, Mr. Hopwood asked the President of the Local Government Board whether his attention had been drawn to the statement by the inspectors in the inquiry into the case of eight children attacked with erysipelas after vaccination at Norwich, as to four of the cases which terminated fatally: "we cannot divest our minds of the strong impression that the lymph used in vaccinating these children must have carried with it the elements of the disease which they subsequently developed;" whether the public vaccinator had been recommended for a award from the Parliamentary grant; whether Dr. Buchanan, the medical officer of the Local Government Board, in his memorandum urged the same vaccinator with using dirty or improperly washed instruments in the processes of vaccination during the years 1876 to 1880, and later; and whether it was any cause by law, in answer to fresh summonses to vaccinate, on the parents of any of the children so attacked to urge their fear of similar risk to the survivors; if not, whether it was proposed by legislation to relieve such parents from the compulsion at present existing.—Mr. Dodson pointed out that the quoted words had reference not to four cases which terminated fatally, but to four cases vaccinated from one child, and of which two did not get erysipelas. Dr. Guy, the public vaccinator, was recommended in 1874, but not in 1876 or 1878, and he was again recommended in 1880, when the objectionable practice previously discovered by the inspector appeared to have been discontinued, inasmuch as it was not again charged. It was no legal defence to a summons for parents of children who had been attacked with erysipelas after vaccination to urge their fear of similar risk to their other children. He was not prepared to assent to the view that because one child happened to have suffered, owing to malpractice, or to some accidental circumstance, therefore all other children should be deprived of the protection which vaccination afforded. At the same time, it was open to the justices in any such case to impose a nominal fine, or to decline to make an order for the vaccination of the child; and he hoped that whenever any such case occurred it would be considered and tenderly dealt with.

### *The War Office Committee.*

Lord Burghley inquired whether it was correct, as stated by Lord Morley at the dinner to the Medical Staff on Nov. 21st, that the War Office Committee was not appointed to inquire into the alleged defective condition of the Army Medical Department during the Egyptian War.—Sir A. Hayter replied that he thought the noble lord's observations must have been misinterpreted. The following were the Secretary of State's instructions to the Committee: "It will be advisable that the Committee appointed to inquire

into the organisations of army hospital corps should extend the scope of its inquiry into the question of hospital management and nursing in the field, as well as the sea transport of sick and wounded. The recent experience in the Egyptian campaign will be most valuable in such an inquiry. The Committee should ascertain what deficiencies, if any, existed in the field or other hospitals, or hospital ships, in that campaign, with a view to future remedy."—Lord Burghley asked when it was likely the report would be presented.—Sir A. Hayter said great efforts would be made to complete it by next session.

### *The Contagious Diseases Acts.*

Mr. Stansfeld gave notice that he will move for correspondence relating to the operation of the Contagious Diseases Acts in Devonport; and also that next session he will again bring forward a resolution in opposition to the Acts.

On Thursday, the Speaker was able to resume his duties in the House.

### *Bengal Gaols.*

Mr. O'Donnell asked what steps had been taken to reduce the mortality in the Bengal gaols, since the last report showed that though less than in the exceptional year of 1879, it was still immensely higher than among the free population of all conditions.—Lord Hartington said that since papers were laid on the table on this subject in the present session, the only additional information that had been received was contained in a despatch from the Government of India, dated July 29th. It was there stated that in consequence of his (Lord Hartington's) despatch in May, a circular address had been issued to the various local centres to ensure greater vigilance in the matter of the mortality returns. The dietary scale now in operation was sufficiently good to keep the prisoners in health. The report stated that the returns of the deaths among the free population could not be relied upon in the same way as those of the deaths in gaols, where every case was strictly recorded. The Government of India had promised to send home annually a general review of the gaol statistics.—Mr. O'Donnell asked that inquiries might be made as to the effect not only of the dietary scale, but also as to the effect of the absence of ventilation and overcrowding in the gaols, and also as to the effect on the health of the prisoners of the habit of heaping together mounds of earth instead of beds.—Lord Hartington said he thought the sanitary condition of the gaols was under the consideration of the Government of India and of the Local Government Board. He would cause inquiry to be made into these allegations.

### *The Artisans' Dwellings Acts.*

Mr. Dodson stated to Sir R. Cross that the attention of suburban sanitary authorities had been called to the evidence given before the Select Committee on these Acts, as to the want of sanitary regulations with regard to some of these dwellings erected outside the jurisdiction of the Metropolitan Board. He would consider whether it was necessary that the powers of local authorities in this respect should be extended.

## Obituary.

PROFESSOR PIRRIE, M.D., LL.D., F.R.C.S. ED., &c.

EMERITUS PROFESSOR WILLIAM PIRRIE died at his residence, in Union-street, Aberdeen, on Nov. 21st, at the age of seventy-five years. The sad announcement was scarcely a surprise to those who knew how he had suffered for the past eight months, at first from an attack of peri-hepatitis, and quite recently from an abscess, the result of an enlarged prostate. Little of wonder need be occasioned by the death of one who has attained to such a venerable age; but those who knew the fine physique, the working qualities, and youthful spirits of Dr. Pirrie were not accustomed to consider him as almost an octogenarian, but as one who had yet the capacity for much good work.

William Pirrie was the son of a small farmer in the parish of Gartly, near Huntly, in the county of Aberdeen, where he was born in 1807. His general education, begun in the

parish school, was carried on in the grammar school, and finished in Marischal College, Aberdeen, where he graduated in Arts. The moderate curriculum then necessary for graduation was completed by Dr. Pirrie in Aberdeen and Edinburgh; and how moderate it really was is illustrated by the fact that only one professorship of a purely medical subject then existed in Aberdeen. In 1828 he became Licentiate of the Royal College of Surgeons, Edinburgh, and in 1829 took his degree as Doctor of Medicine. While in Edinburgh he had the advantage of a close connexion with his *beau idéal*, Liston, for whose memory he throughout life cherished the warmest regard. Liston he considered as the greatest of British surgeons, and amongst his wonderful collection of instruments there was none so prized as the amputating knife formerly used by his master. The manner in which the ambidextrous surgeon held his knife while operating was a subject which Dr. Pirrie would debate with warmth; and his oil painting of Liston's hand, showing the method considered proper, was valued much above its merits as a work of art. After a year of study in Paris, Dr. Pirrie returned to Aberdeen, and in 1830 was appointed Lecturer on Anatomy and Physiology in King's and Marischal Colleges. Thus began his career as a teacher, which was destined to last for over half a century and to win for him a great name. Till 1839 he continued this lectureship; and ever afterwards attributed his success as a surgeon in great part to the thorough acquaintance with anatomy then obtained. In 1839 the chairs of anatomy and surgery were founded, and Dr. Pirrie, who had already a large surgical practice, was elected the first professor of surgery. From that time till a few months ago he maintained the dignity and the usefulness of the chair in such a manner as has done more to establish and enhance the fame of the Aberdeen School than has the work of any other man connected with it. It is as a teacher that Dr. Pirrie will be remembered; in the lecture-room he was *facile princeps*. From the first he gave himself with rare devotion to the work which he thought so honourable; his interest and enthusiasm were in the highest degree contagious; his commanding presence and his confident tone gave weight to his statements; while his practical method of teaching was no new development in response to modern clamour, but the system which he had consciously and from the first maintained as the most useful. His readiness of speech allowed him to dispense with manuscripts; but as a consequence he was somewhat given to repetition, though seldom in other than important points. Occasionally, in the hurry of thought and articulation, delightful "bulls" were perpetrated, which his students would not willingly have missed, and a string of adjectives was formed which would not always bear analysis. Many a story is told of the surgery class when old Aberdeen students get together, but the mirth is always leavened with respect and even love for him who is now gone, and, indeed, the most delightful reminiscences of student life in Aberdeen somehow connect themselves with his class. As we have said, his manner of teaching was chiefly demonstrative, and for this purpose he had brought together a number of specimens and instruments, the latter especially which were quite unique. No other collection of surgical instruments in the kingdom, in the hands of any practitioner, equalled that of Dr. Pirrie. Some of his pathological specimens were most valuable; and how delighted he was to expatiate upon these all Aberdeen graduates will remember. Upon this practical method Dr. Pirrie was able to bring to bear an amount of knowledge of the history and literature of his subject, which must be most exceptional; and we believe that the acquaintance with all that has been written on surgery, which Dr. Pirrie showed, would have given him high rank as an author had he chosen to publish on the subject. He has been known to hint his intention of publishing a "History of Surgery" could he but find time, and it is just possible that he had advanced so far with this work as to make his labours available to others; it is almost certain that had he been spared to the profession but a little longer such a history would have been forthcoming. An old assistant and house-surgeon of Dr. Pirrie's writes:—"I verily believe he knew Paré by heart. He certainly knew everything worth knowing that was written on surgery from the beginning of time to the eighteenth century." To his lifelong habit of early rising Dr. Pirrie was probably indebted for his almost encyclopædic knowledge of his subject. It was his custom to devote four hours every morning to reading and writing, and this custom he maintained till near the end. As an

author the late Professor is best known by his "Principles and Practice of Surgery," a work which has passed through three editions in this country, and as many as five editions in America. Some years ago, when acupuncture was first introduced by the late Sir James Simpson, Dr. Pirrie espoused the subject rather warmly, and, along with his colleague Dr. Keith, wrote a pamphlet on the subject, besides putting the method largely in practice. Mr. Lister's system has in great measure obviated the necessity for this method of closing bloodvessels; but till the last Dr. Pirrie insisted upon the importance and value of Simpson's discovery. His contributions to THE LANCET were numerous, and so late as August we published his last contribution to medicine, in his address to the North of Scotland Medical Association, of which he was president. Throughout his long career Dr. Pirrie has conducted a practice so large that only his lion-like strength could be equal to it. Unfortunately for his own comfort, he did not confine himself to surgery, and, indeed, was to the last in great part occupied as a general practitioner. Ill-natured remarks were frequently made regarding this feature of his work, but we can at least admire the determination with which he struggled through an almost overwhelming amount of toil. His practice was, perhaps, the most extensive ever held by one man north of Edinburgh, and, if we are not mistaken, so was his income. Both these circumstances gave him a justifiable pride, but it was only his closer friends who knew of this satisfaction. As an operator he was, perhaps, scarcely brilliant, but a man decided in action, and whose every cut had its decided purpose. It was a treat to see him trim a stump: one cut did this.

During his long and distinguished career Professor Pirrie had many honours heaped upon him. He was peculiarly gratified when, in 1875, the University of Edinburgh conferred upon him the honorary degree of LL.D. The Clinical Society of London a few years ago elected him an honorary member, and since 1877 he has been surgeon in Scotland to H.R.H. the Prince of Wales. Perhaps the honour which he valued most was the warm regard of his students, and many evidences of this he continued to receive from men who in after life had been distinguished and useful. Students are not usually slow in detecting their best friends in the professoriate, and they felt sure of their interests being regarded so long as Professor Pirrie had a seat in the Senatus. He warmly supported his colleague, Dr. Struthers, in his endeavour to raise the necessary funds to provide bursaries for the medical students, and in every way assisted by his counsel and influence the friends of progress in the teaching of medicine. His enthusiasm in this direction was well shown in the recent establishment of the Chair of Pathology, as it is well known that Sir Erasmus Wilson's regard for his old friend induced him to place reliance on Dr. Pirrie's views regarding the direction of his munificence.

So long ago as 1847 Dr. Pirrie was appointed surgeon to the Aberdeen Infirmary, an office which he held till, in 1880, he resigned his position as senior surgeon, and was elected consulting surgeon to the institution. His work at the infirmary he looked upon as secondary only to the work of his Chair, and the regularity and devotion with which he carried out these duties were remarkable when the amount of his practice was considered. Of such a practical man it is needless to say that he thoroughly entered into the clinical part of his teaching. Not contented with the enormous field of labour occupied by him professionally, Dr. Pirrie found time to devote to many objects of philanthropic or religious interest. Several local institutions, and more especially the Young Men's Christian Association, owe much of their vitality to his advice and assistance, while in private he was most helpful to many struggling creatures.

Dr. Pirrie leaves a widow and a family of seven. Of these, three sons are in the medical profession: Dr. William Pirrie of Bournemouth, Dr. George Pirrie of the Indian Army, and Dr. Gordon Pirrie of Aberdeen, the last of whom, along with Dr. Burridge, attended the deceased professor during his last illness.

Dr. Pirrie was accorded a public funeral by the authorities, and how well the public sentiment had been interpreted was shown by the enormous concourse which accompanied the remains from Marischal College, to which, in accordance with an old custom, the body had been removed. The Lord Provost, Magistrates and Council, the University authorities, a large number of students, and the members of the Medico-Chirurgical Society walked in procession, while the sympathizing crowd was supposed to number thirty thousand.

## BRIGADE-SURGEON T. M. BLECKLEY, M.D., C.B.

DR. BLECKLEY was the son of the late Rev. John Bleckley, M.A. He was born in 1828, was educated at Trinity College, Dublin (B.A. 1852, M.D. 1863, M.A. and LL.B. 1872), and was hon. F.K.Q.C.P. He entered the Army Medical Department as Assistant-Surgeon in 1854, became Surgeon-Major in 1863, and retired on half-pay in 1880 as Brigade-Surgeon. He served in the Crimean campaign, 1855 (medal, with clasp, and Turkish medal), and in the Ashantee war, 1873-4 (mentioned in despatches, and medal). When secretary to the Inspector-General of Hospitals, British Forces, in India, he was twice thanked by the Governor-General in Council for professional services. He married in 1865 Lydia, daughter of Andrew Hamilton, Esq., of Cootown, co. Donegal, and was created C.B. in 1874. The deceased had long suffered from grave incompetency of the aortic valve. This condition induced a train of distressing symptoms, which, although they were borne with much exemplary resignation, had of late deprived life of all its savour. He died of syncope on November 23rd at his residence, Lorne House, Upper Norwood, leaving a widow and five children to cherish the memory of a devoted husband and father. Outside his family circle, many will lament the loss of a friend whose genial, kind, and gentle disposition supplemented a blameless life.

## Medical News.

**APOTHECARIES' HALL.**—The following gentlemen passed the examination in the Science and Practice of Medicine, and received certificates to practise, on Nov. 23rd:—  
Cunnington, Cecil W., Bartholomew-road, Kentish Town.  
Peskett, Alfred Freeman, Leyton, Essex.  
Serjeant, George, Lewannick, Cornwall.  
Tiseman, Arthur Lumley, Howden, Yorkshire.

The following gentlemen also on the same day passed the Primary Professional Examination:—  
Arthur Edwin Huxtable, Charing-cross Hospital; Ernest William Phillips, Guy's Hospital; Fredk. Owen Y. Roosmale Cocq, University College.

The following gentleman passed the examination and received a certificate to practise on Nov. 16th:—  
Dalton, Arthur John, Albert-road, South Norwood.

THE proceeds of the Hospital Sunday collection at Hastings amount to £517.

THE foundation-stone of the new infirmary at Chelmsford was laid on Tuesday.

LAST week at Greyabbey, county Down, the skeleton of an Irish elk was discovered by some men working in a bog. The antlers from each extremity measure about ten feet.

COLLECTIONS were taken last Sunday in most of the churches in Belfast on behalf of the Royal Hospital of the town.

THE cutlers and surgical instrument makers of London have resolved to form themselves into a trade association.

MR. TIMOTHY L. WALFORD, M.R.C.S., L.S.A.L., late medical officer of the workhouse of the Reading Union, has received a superannuation allowance of £87 a year.

OVARIOTOMY IN AN INFANT.—Dr. Hingston, of Montreal, recently removed an ovarian tumour from a child two years of age. The patient was doing well at last account.

MISS ELIZABETH KNOX has left £250 to the Adelaide Hospital, £200 to the City of Dublin Hospital, £200 to Meath Hospital, £200 to the Hospital for Incurables, and £150 to the Rathdown Hospital.

THE GUEST HOSPITAL, DUDLEY.—The report of the general committee, read at the annual meeting of the subscribers and friends of this institution held on Nov. 21st, stated the income of the past year to be £3017, and the expenditure £3224. The benefits of the charity had been participated in by a larger number of patients than in any year, with the exception of 1880. Last Hospital Sunday 1500 visits from friends of the patients were paid, and the sum collected on that occasion at the doors amounted to £8. 5s.

THE public charitable hospitals of the city of New York contain a total of 5108 beds, the largest being the Emigrant Hospital with 1200 beds, the Charity Hospital coming next with 990 beds. The various private hospitals have a capacity of 2302, and the lunatic hospitals of about 3000.

THE QUEEN AT NETLEY.—Her Majesty, accompanied by the Duke of Connaught, the Duke of Albany, and Princess Beatrice visited Netley Hospital on Wednesday. The Queen, conducted by General Sir Charles Pearson and the medical staff, stopped at the bed of every wounded soldier, addressing to him words of sympathy and bestowing upon him a decoration. The Royal party returned to Windsor in the evening.

THE ROYAL SOCIETY.—At the anniversary meeting of the Fellows of the Royal Society, held on Thursday at Burlington House, the Copley Medal, awarded at a previous meeting, was presented to Professor Cayley, F.R.S., of Cambridge, for his numerous researches in pure mathematics; and a Royal Medal to Professor Flower, F.R.S., of the Royal College of Surgeons, for his valuable contributions to the morphology and classification of the mammalia and to anthropology.

A CENTENARIAN.—Miss Sarah Apted, residing at Fern Villa, Garlands-road, Redhill, attained on the 29th ult. the great age of 100 years, she having been born at Reigate on December 2nd, 1782. There is no doubt about the authenticity of her age, as the entry of her birth and the date may be found in the books of Reigate Parish Church. We are informed by Mr. W. A. Berridge that this venerable old lady enjoys very fair health, gets up and dresses herself every day, has a good appetite, and occasionally takes and enjoys a glass of port. She has only one useful eye, having lost the other, as she says, "from inflammation, in the month," meaning in the first month of her life.

## BOOKS ETC. RECEIVED.

- BLACKIE & SON, London, Glasgow, Edinburgh, & Dublin.  
The Imperial Dictionary of the English Language: a complete Encyclopedic Lexicon, Literary, Scientific, and Technicological. By John Ogilvie, LL.D. New Edition, carefully Revised and greatly Augmented. Edited by Charles Annandale, M.A. Illustrated by above 3000 Engravings printed in the text. Vol. IV. With Supplement and Appendix.
- BLAKISTON, SON, & Co., Philadelphia.  
Speech and its Defects. By Samuel O. L. Potter, M.A., M.D. pp. 117.
- CASSELL, PETER, GALPIN, & Co., London, Paris, and New York.  
The History of the Year: a Narrative of the chief events and topics of interest from Oct. 1st, 1881, to Sept. 30th, 1882. pp. 568.

## Medical Appointments.

Intimations for this column must be sent DIRECT to the Office of THE LANCET before 9 o'clock on Thursday Morning at the latest.

BATESON, J. F., M.B., C.M. Edin., has been appointed Resident House-Surgeon to the Liverpool Royal Infirmary.  
BEATLEY, WM. CRUMP, M.B. Durh., M.R.C.S., L.S.A. Lond., has been appointed Resident Medical Officer to Charing-cross Hospital.  
BICKLE, L. W., L.R.C.P., M.R.C.S., has been appointed Non-resident House-Physician to St. Thomas's Hospital.  
BRADSHAW, T. R., M.D. Dub., has been appointed Resident House-Surgeon to the Liverpool Royal Infirmary.  
BRAILEY, WM. ARTHUR, M.D. Camb., M.R.C.S., has been appointed Assistant Ophthalmic Surgeon to Guy's Hospital.  
COOPER, G. F., M.R.C.S., L.R.C.P., has been appointed Assistant House-Surgeon to St. Thomas's Hospital.  
COTTER, JEREMIAH, M.D. M.Ch., has been appointed Assistant-Surgeon to the Cork North Infirmary.  
CREMEN, P. J., M.D., has been elected Physician to the Cork North Infirmary.  
EAMES, JOHN DAVEY, L.R.C.P. Lond., M.R.C.S., has been appointed Medical Officer to the Workhouse of the Driffield Union, vice Scotchburn, deceased.  
FELL, W., M.A., M.B. Oxon., L.R.C.P., M.R.C.S., has been appointed Assistant Non-resident House-Physician to St. Thomas's Hospital.  
GRACIE, C. B., M.R.C.S., has been appointed Resident House-Physician to the Liverpool Royal Infirmary.  
HAIG-BROWN, C. W., M.R.C.S., L.S.A. Lond., has been appointed House-Surgeon to St. Thomas's Hospital.  
HERN, WM., M.R.C.S., L.D.S. Eng., has been appointed Demonstrator of Cohesive and Contour Filling to the Dental Hospital of London.  
HIGGINS, CHARLES, F.R.C.S. Eng., has been appointed Ophthalmic Surgeon to Guy's Hospital, vice C. Bader, resigned.  
JONES, D. LLEWELLYN, M.R.C.S., has been appointed Resident Assistant Surgical Officer to Charing-cross Hospital.  
JONES, WANSBROUGH, M.A., M.B. Oxon., M.R.C.S., has been appointed House-Physician to St. Thomas's Hospital.  
LOWE, T. P., M.R.C.S., has been appointed Resident House-Physician to the Liverpool Royal Infirmary.  
MACLEAN, CHARLES, M.D., M.Ch. Aber., has been appointed Medical Officer to the Epworth District of the Thorne Union.  
MARLOW, F. W., M.R.C.S., L.S.A. Lond., has been appointed Ophthalmic Assistant to St. Thomas's Hospital.  
MILLIGAN, WILLIAM, L.R.C.P. Ed., M.R.C.S., L.S.A. Lond., has been appointed Medical Officer to the South Norwood District of the Croydon Union.  
NETTLESHIP, EDWARD, F.R.C.S. Eng., has been appointed Assistant-Surgeon to the Royal London Ophthalmic Hospital, Moorfields, vice Lyell, deceased.

RIDPATH, D., M.D., C.M., has been appointed Medical Officer of Health for the Urban Sanitary District of Great Driffield.  
SUTTON, S. W., M.B. Lond., M.R.C.S., L.R.C.P., has been appointed Resident Accoucheur to St. Thomas's Hospital.  
THOMPSON, EDMUND JOHN, M.R.C.S., L.S.A. Lond., has been appointed Medical Officer to the Sixth District of the Ashby-de-la-Zouch Union.  
TREASURE, W. B. C., L.S.A. Lond., has been appointed Resident Assistant Medical Officer to Charing-cross Hospital.  
TYRRELL, WALTER, L.R.C.P. Lond., M.R.C.S., has been appointed Junior Anæsthetist to St. Thomas's Hospital.  
WELLS, A. E., M.B. Lond., M.R.C.S., L.R.C.P., has been appointed House-Physician to St. Thomas's Hospital.  
WHITE, E. F., M.R.C.S., L.S.A. Lond., has been appointed House-Surgeon to St. Thomas's Hospital.  
WIGAN, C. A., M.R.C.S., L.S.A. Lond., has been appointed Resident Obstetrical Officer to Charing-cross Hospital.  
WILLIAMS, E. R., M.R.C.S., L.R.C.P. Lond., has been appointed Assistant Medical Officer to the Derby Amalgamated Friendly Societies' Medical Association.  
WILSON, A. H., M.R.C.S., has been appointed Resident House-Surgeon to the Liverpool Royal Infirmary.  
WRIGHT, GEORGE ARTHUR, B.A., M.B. Oxon., F.R.C.S. Eng., has been elected Honorary Assistant-Surgeon to the Royal Infirmary, Manchester, vice Mr. J. Hardie, promoted to Honorary Surgeon.  
WYBORN, S. BARGRAVE, M.R.C.S., L.S.A. Lond., has been appointed Resident Surgical Officer to Charing-cross Hospital.

## Births, Marriages, and Deaths.

### BIRTHS.

DOUGLAS.—On the 24th ult., at Newbury, the wife of W. T. Parker Douglas, B.A., M.B. Cantab., of a son.  
GANDY.—On the 23rd ult., at Hill Top, Gipsy-hill, S.E., the wife of William Gandy, M.R.C.S., of a daughter.  
ILES.—On the 23rd ult., at Watford, the wife of Wilson Iles, M.D., of a son.  
MACSWINEY.—On the 16th ult., at Corradino, Malta, the wife of Surgeon-Major MacSwiney, M.D., Army Medical Department, of a daughter.  
ORR.—On the 21st ult., at Worlston, Wellingboro', the wife of James W. Orr, of a son.  
WEST.—On the 25th ult., at Wimpole-street, W., the wife of Dr. S. West, of a daughter.

### MARRIAGES.

BATCHELOR—HAWKINS.—On October 12th, at Port Elizabeth, Cape Colony, George Arthur Batchelor, M.B., &c., late Resident Physician of London Hospital, to Beatrice, eldest daughter of the late Dr. J. S. Hawkins, of London.  
MACDONALD—MACDONALD.—On the 2nd ult., at the Free Church, Esplanade, Bombay, by the Rev. Robert Jeffrey, Duncan Macdonald, B.Sc., M.D., Professor of General Biology, Elphinstone College, Bombay, to Mary H. Macdonald, third daughter of the late Rev. John Macdonald, Free Church, Fearn, Ross-shire.  
MULLIN—FINCO.—On the 28th ult., at the Church of Our Lady of Seven Dolours, James Mullin, M.A., M.D., M.Ch., L.M., late Q.C.I., of Cookstown, to Annie, widow of the late Eusebio Finco, of Rome.  
POPPELWELL—LEWIS.—On the 23rd ult., at St. Peter's Church, Harrogate, George Ball Poppelwell, Brigade Surgeon, Army Medical Department (Retired), to Ann, widow of Samuel Lewis, Esq., of Rowley Regis, Staffordshire, elder daughter of the late Joseph Leing, Esq., of Tynemouth, Northumberland.  
ROBERTSON—FRASER.—On the 21st ult., at Tornaveen, Aberdeenshire, Douglas Argyll Robertson, M.D., F.R.C.S.E., of Charlotte-square, Edinburgh, to Frances Garden Carey, youngest daughter of Wm. N. Fraser, Esq., of Tornaveen.  
SMITH—CHAMPNEYS.—On the 26th ult., at the Parish Church, Stepney, Dr. Frederick A. A. Smith, son of Dr. Smith, of Portland House, Cheltenham, to Anna Maria Mundell, only daughter of Alexander Mundell Champneys, M.R.C.S., of Hanbury-street, London.  
STUART—AINSLIE.—On the 21st ult., at Lansdowne-crescent, Edinburgh, T. P. Anderson Stuart, M.D., Professor of Anatomy in the University of Sydney, to Lizzy, third surviving daughter of Archibald Ainslie, Esq., of Doderidge, East Lothian.

### DEATHS.

BLECKLEY.—On the 23rd ult., at Lorne House, Upper Norwood, T. M. Bleckley, M.D., C.B., Brigade Surgeon, Army Medical Department, aged 52.  
BRAID.—On the 22nd ult., at Lawnswood, Burgess-hill, Sussex, after a few days' illness, James Braid, M.D. Edin., aged 60.  
BUCKLE.—On the 19th ult., John Buckle, M.R.C.S., of Great Bardfield, Essex, aged 26.  
CHADWICK.—On the 19th ult., at Beckenham, Kent, of typhoid fever, James Chadwick, only son of James Chadwick, of York, and late student at Guy's Hospital, S.E., aged 19.  
CROSS.—On the 18th ult., at Carlton House, Scarborough, Richard Cross, M.D., F.R.C.S., J.P., aged 64. R.I.P.  
MACK.—On the 21st ult., Robert Litguard, son of Robert Mack, L.R.C.S.I., L.S.A., of 26 and 28, St. Paul's-road, N.  
PAUL.—On the 20th ult., at Kelso, James, son of J. Paul, M.D., of Barnes, Surrey, aged 39.  
PEARSON.—On the 20th ult., at St. Luke's-road, Bayswater, Francis Pearson, Deputy Surgeon-General, Bengal Army (retired), aged 56.  
PIRRIE.—On the 21st ult., at 253, Union-street, Aberdeen, William Pirrie, M.D., LL.D., Emeritus Professor of Surgery in the University of Aberdeen, and Surgeon in Scotland to H.R.H. the Prince of Wales. Friends will kindly accept this (the only) intimation.  
WORBOYS.—On the 23rd ult., at Blackfriars-road, Thomas Sanders Worboys, M.R.C.S., L.S.A., aged 45.

N.B.—A fee of 5s. is charged for the insertion of Notices of Births, Marriages, and Deaths.

# Medical Diary for the ensuing Week.

Monday, Dec. 4.

AL LONDON OPHTHALMIC HOSPITAL, MOORFIELDS.—Operations, 10½ A.M. each day, and at the same hour.  
 AL WESTMINSTER OPHTHALMIC HOSPITAL.—Operations, 1½ P.M. each day, and at the same hour.  
 TROPOLITAN FREE HOSPITAL.—Operations, 2 P.M.  
 AL ORTHOPEDIC HOSPITAL.—Operations, 2 P.M.  
 MARK'S HOSPITAL.—Operations, 2 P.M.; on Tuesday, 9 A.M.  
 YAL INSTITUTION.—5 P.M. General Monthly Meeting.  
 EDICAL SOCIETY OF LONDON.—8.30 P.M. Dr. Heneage Gibbes will give a Demonstration on Bacilli and on the manner of Staining them.—Dr. C. Theodore Williams, "On a Case of Bronchiectasis treated by Tapping."

Tuesday, Dec. 5.

Y'S HOSPITAL.—Operations, 1½ P.M., and on Friday at the same hour.  
 ESTMINSTER HOSPITAL.—Operations, 2 P.M.  
 EST LONDON HOSPITAL.—Operations, 3 P.M.  
 THOLOGICAL SOCIETY OF LONDON.—8.30 P.M. The following specimens will be shown:—Fatty Degeneration of Walls of the Heart; Acute Dilatation of Stomach; Photographs and a Living Patient with Ostia Deformans; Congenital Malformation of the Heart; Stricture of Intestine; Tubercles of Liver; Joints from a Case of Scarlet Fever; Malformation of Heart; Excessive Deformity from Rachitic Osteomalacia; Disseminated Polypi of Colon; Polypus of Rectum; Polypus of Small Intestine; Disseminated Abscesses in Liver of Python and of Kangaroo.

Wednesday, Dec. 6.

ATIONAL ORTHOPEDIC HOSPITAL.—Operations, 10 A.M.  
 IDDESEX HOSPITAL.—Operations, 1 P.M.  
 C. BARTHOLOMEW'S HOSPITAL.—Operations, 1½ P.M., and on Saturday at the same hour.  
 T. THOMAS'S HOSPITAL.—Operations, 1½ P.M., and on Saturday at the same hour.  
 T. MARY'S HOSPITAL.—Operations, 1½ P.M.  
 ONDON HOSPITAL.—Operations, 2 P.M., and on Thursday and Saturday at the same hour.  
 GREAT NORTHERN HOSPITAL.—Operations, 2 P.M.  
 AMARITAN FREE HOSPITAL FOR WOMEN AND CHILDREN.—Operations, 2½ P.M.  
 NIVERSITY COLLEGE HOSPITAL.—Operations, 2 P.M., and on Saturday at the same hour.—Skin Department: 1.45 P.M., and on Saturday at 9.15 A.M.  
 PIDEMIOLOGICAL SOCIETY OF LONDON.—8 P.M. Dr. Edward C. Seaton, "On the Influence of Small-pox Hospitals, illustrated by the recent behaviour of Small-pox in Nottingham."  
 BSTRICTAL SOCIETY OF LONDON.—3 P.M. Specimens will be shown by Dr. Cleveland, Dr. Edis, Dr. Galabin, and others.—Dr. Hopkins Walters, "On a Case of Post-partum Avulsion of the Uterus, Right Ovary, and Fallopian Tube; followed by recovery."—Dr. A. Wynn Williams, "On a Case of Ruptured Perineum; improved method of operating."—Dr. Edis, "On a Case of Epithelioma of the Cervix Uteri, Pregnancy, Cæsarian Section; Recovery."—Mr. J. Knowsley Thornton, "On a Case of Extirpation of Uterus and Appendages for Epithelioma of the Cavity."

Thursday, Dec. 7.

ST. GEORGE'S HOSPITAL.—Operations, 1 P.M.  
 ST. BARTHOLOMEW'S HOSPITAL.—1½ P.M. Surgical Consultations.  
 CHARING-CROSS HOSPITAL.—Operations, 2 P.M.  
 CENTRAL LONDON OPHTHALMIC HOSPITAL.—Operations, 2 P.M., and on Friday at the same hour.  
 HOSPITAL FOR WOMEN, SOHO-SQUARE.—Operations, 2 P.M.  
 NORTH-WEST LONDON HOSPITAL.—Operations, 2½ P.M.  
 HARVEIAN SOCIETY.—Harveian Lectures: Mr. Henry Power, "On Ophthalmic Medicine and Surgery in relation to General Practice."

Friday, Dec. 8.

ST. GEORGE'S HOSPITAL.—Ophthalmic Operations, 1½ P.M.  
 ST. THOMAS'S HOSPITAL.—Ophthalmic Operations, 2 P.M.  
 ROYAL SOUTH LONDON OPHTHALMIC HOSPITAL.—Operations, 2 P.M.  
 KING'S COLLEGE HOSPITAL.—Operations, 2 P.M.  
 CLINICAL SOCIETY OF LONDON.—Mr. Godlee, "On Three Cases of Intussusception in Infants treated by Abdominal Section."—Dr. Coxwell, "On the Case of a Child with Symptoms resembling those of Myxedema" (patient will be shown).—Mr. Nunn, "On a Case of Necrosis of the Hyoid Bone and Larynx."—Mr. Davies-Colley, "On a Case of Enormous Enlargement of the Lower Lip, cured by Operation."—Cases of Pseudo-hypertrophic Paralysis in Adults will be shown by Dr. T. H. Green and Dr. J. K. Fowler.

Saturday, Dec. 9.

KING'S COLLEGE HOSPITAL.—Operations, 1 P.M.  
 YAL FREE HOSPITAL.—Operations, 2 P.M.

## METEOROLOGICAL READINGS.

(Taken daily at 5.30 a.m. by Steward's Instruments.)

## Notes, Short Comments, and Answers to Correspondents.

*It is especially requested that early intelligence of local events having a medical interest, or which it is desirable to bring under the notice of the profession, may be sent direct to this Office.*

*All communications relating to the editorial business of the journal must be addressed "To the Editor."*

*Lectures, original articles, and reports should be written on one side only of the paper.*

*Letters, whether intended for publication or private information, must be authenticated by the names and addresses of their writers, not necessarily for publication.*

*We cannot prescribe, or recommend practitioners.*

*Local papers containing reports or news-paragraphs should be marked.*

*Letters relating to the publication, sale, and advertising departments of THE LANCET to be addressed "To the Publisher."*

### SEASIDE CONVALESCENT HOMES FOR CHILDREN.

THIS movement is making progress in Germany, and the result of this year's work having encouraged the promoters of the scheme to extend the circle of their operations, a large institution is intended to be built at Norderney. The Emperor of Germany has contributed £12,500 on the understanding that a like sum is collected before the end of 1883 by means of the voluntary offerings of the German nation. The plan of the institution does not include (according to the *Cologne Gazette*) the strictly gratuitous support of the children, a small weekly payment being expected. It is thought that this institution will be opened in 1884.

*Medicus.*—Our correspondent would seem, from the statement forwarded to us, to have good ground for refusing to continue to carry out his part of the contract. But the questions are legal. A good arbitration would be the best way out of the difficulty.

### "VICARIOUS MENSTRUATION."

*To the Editor of THE LANCET.*

SIR,—In answer to a letter in your issue of to-day, under the title of "Vicarious Menstruation," will you give me space for a few remarks. It seems to me that Dr. Morris has jumped to the conclusion that he has to deal with a case of vicarious menstruation, with scarcely any grounds for doing so. He appears to have called his case one of vicarious menstruation because he was at a loss to explain the hæmorrhage otherwise. "She does not appear to be plethoric and the heart sounds are healthy," he says, as if these were the only causes (besides vicarious menstruation) of hæmorrhage from the parts he mentions. From what I gather from his letter I conclude that the hæmorrhage occurred in August only, and that there has been no monthly recurrence. Because hæmorrhage occurred last August from the eyelids, nose, and mouth of a woman who appears healthy, except that she does not menstruate regularly, surely we are not justified in saying that it is a case of vicarious menstruation. The fact that the menstrual flow is irregular and scanty does not favour the idea that hæmorrhage was "vicarious of menstruation." If the menstrual flow had been natural before and had failed or diminished at the time of the hæmorrhage, the fact would have been worth mentioning in favour of its being so. The fact that the pain in the right eye is constant, points rather to some local cause of the hæmorrhage. It is as well that Dr. Morris has "determined" to watch the case; and it will be interesting to know whether the hæmorrhage recurs, and at what intervals. Also whether it is accompanied by any of the symptoms which commonly precede or accompany the menstrual flow. Should hæmorrhage occur again I should advise the use of hæmeline.

I remain, Sir, yours truly,

London, Nov. 18th, 1882.

R. J. COLLYNS.

## THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

THIS school (says the *New York Medical Record*) had a very successful inauguration at Chickering Hall on November 4th. Dr. Wm. A. Hammond presided, and delivered the opening address. He said that the course of study for medical students in American colleges rarely lasts more than three years, and in that time it is simply impossible for a student to gain sufficient knowledge to enable him to practise his profession intelligently and safely for his patients. If the student wishes to excel, and is wealthy, he may go to Europe and there complete his studies, or, in some instances, he may enter a hospital and there gain a practical knowledge of his work; but the great majority are obliged to go out into the world without being well grounded in the principles of their profession. Medical science, too, is progressive, and it is difficult for a practitioner to keep pace with the progress of the science. It is not agreeable for him to attend the lectures to the undergraduates, and even if it were, he would not get what he wants there. It is to provide for the wants of such men and to give them a higher clinical education than they can secure in our colleges that the Post-graduate School has been organised.

*Dr. G. Stanley Murray.*—We should have a published report of the case before the county court judge. It is clearly not desirable to comment on an *ex parte* statement.

## THE TREATMENT OF BRONCHOCELE.

To the Editor of THE LANCET.

SIR,—Since no notice has been taken of the fatal case of cystic bronchocele reported by Mr. Herbert Smith in your issue of Nov. 4th, allow me to point out that the treatment recommended by Dr. Mackenzie was not pursued, since Mr. Smith employed a dilution—or, as he calls it, a solution—of iron tincture, which, in the absence of any statement as to its free acid having been neutralised, is, even without the consideration of the presence of alcohol, a very different thing from an aqueous solution of the neutral salt, as recommended by Dr. Mackenzie. I have myself employed this treatment repeatedly, and have never had a fatal case; nor do I know of any on record when Mackenzie's treatment has been exactly pursued, except the one reported by him, in which immediate death resulted from entrance of air into a vein. The precautions he has since prescribed should effectually prevent recurrence of such an untoward accident. As a matter of practice it is also well, having found by experiment with a grooved needle that the case is cystic, to continue then and there the curative treatment by injection. In this instance two tapplings and aspirations had been performed at short intervals before the final operation. Beyond all this, it must be very clear to anyone who reads the case that there was not a free exit for the matter, since after death the cyst ruptured, discharging half a pint of fetid pus into the mouth. In point of fact, the success of the treatment in destroying the blood-cyst and promoting suppurative is strikingly exemplified, and the patient, as the French surgeon had it, "died cured."

It may be useful to point out that the writer of the article on goitre in Dr. Quain's recently published Dictionary of Medicine makes the same mistake as Mr. Smith in recommending the tincture. He further gives the opinion that in the treatment of goitre by seton the patient may continue his ordinary occupation. I can only hope that no surgeon will follow this advice, certainly not without taking note of the temperature of his patient, which, until suppuration is established, generally varies from two to four degrees above the normal.—I am, Sir, your obedient servant,

Nov. 13th, 1882.

CHIRURGUS.

P.S.—Mr. Herbert Smith's reference to Vol. II. of the Clinical Transactions is inaccurate, or inaccurately printed. It should be Vol. VII.

*B.A. Dub.*—The name is not to be found either in the Medical Register or the Medical Directory for the present year.

*Mr. Williams (Portsmouth).*—The paper is marked for insertion.

*Dr. Lerat (Nantes).*—We cannot exchange.

## DIET OF NURSING MOTHERS.

To the Editor of THE LANCET.

SIR,—I read with much interest your annotation on milk and alcohol. The use of stimulants and the best diet for nursing on is frequently brought before us. I have usually advised as the most suitable that mode of living which experience has taught the mother has kept her in the best health when not nursing, and such an admixture of fruit and vegetables as will prevent the necessity of taking aperient medicines. Stimulants are to be looked upon as condiments. If a glass of ale or stout makes her enjoy her meals, and consequently digest them better, it is to be preferred to water, which would make them less enjoyable, and diminish the salivary secretion. The popular custom of drinking stout to increase the flow of milk is an error; if it does act as a lactagogue, it is like feeding cows on brewers' grains—the quantity of milk is greater, but with the sacrifice of its quality and nutritive value, and therefore no gain to the infant. The use of stronger stimulants is most to be deprecated. The best drink, I believe, for a nursing woman, to stimulate the glands and produce a more abundant and, at the same time healthy secretion of milk, is thin barley gruel made with milk.

November 14th, 1882.

I am, Sir, yours faithfully,

D. H. G.

## EXAMINATIONS AT THE ROYAL COLLEGE OF SURGEONS.

At the half-yearly examination for the Fellowship of the College, on the 23rd, 24th, and 25th ult., there were sixteen candidates, of which number nine are reported to have been successful. At the corresponding period last year there were twenty-five candidates, seventeen of whom were referred for one year. The following were the questions on Pathology, Therapeutics, and Surgery submitted to the candidates at the written examination on the 23rd ult., when they were required to answer all four questions, between 1.30 and 5.30 P.M. :—

1. What do you understand by the term organisation of blood-clot? Describe fully the process to which, in your opinion, the expression may be applied.
2. Describe the causes, and discuss the treatment, of secondary hemorrhage after amputation through the middle of the thigh.
3. What are the diseases to which the thyroid gland is liable? Give their diagnosis and treatment.
4. Describe the various surgical affections consequent on locomotor ataxy and their diagnosis.

The names of the successful candidates cannot be published until they have been submitted to the Council, at its next meeting on the 14th instant.

## ON TRANSFUSION.

To the Editor of THE LANCET.

SIR,—Undoubtedly I should feel, and I really think I do feel, a sense of obligation to Mr. W. H. Fenton-Jones for so kindly, so courteously, and with so much generosity and disinterestedness favouring your readers with his opinions on my transfusion apparatus. And especially so as he has gone to the great trouble of elaborating that opinion from the evidence furnished by an imperfect woodcut.

One little circumstance, however, unfortunately, in a small but appreciable degree, detracts from the weight of his erudition. The London Hospital is the head-quarters of the "salino-alcoholic" disciples. There it is that "the many objections inherent in blood transfusion" are considered to render it an operation which should never be performed, at least not whilst salino-alcoholic fluid is the hobby. There also it is that Mr. Jennings' "syphon"—which I have had the pleasure of seeing and of hearing described by himself—is used; where, with it, the "fluid" has stood the test of two cases, which is, no doubt, an unnecessarily prolonged succession of successes to establish the foregone conclusion that the "salino-alcoholic" fluid is the only fluid, and Mr. Jennings' "syphon" the only instrument. Mr. W. H. Fenton-Jones is, or was very recently, resident accoucheur at the London Hospital.

My indebtedness would have been, if possible, enhanced had he kindly gone to the further trouble of avoiding an imaginary quotation from my article. He says, "I cannot conceive that it is a very facile matter, alone and unassisted, to retain both cannulae in the veins of the donor and receiver of blood with one hand, &c." Certainly it would not be a facile matter. It would be a feat which I for one should neither attempt nor suggest. What I wrote was that with my apparatus skilled assistance was not necessary. The operation, if to be performed at all by the country practitioner, must be such that available assistance may suffice where skilled assistance is unobtainable.

Mr. Jones considers my "diverticulum" ingenious, but that "surely it may be a source of some trouble in that it will want some dexterity to empty the branch of the air it originally contained." I stated that all that was needed was to charge the instrument with the air chamber downwards. The "trouble" and "dexterity" requisite for this procedure would, I think, not place any very severe strain on the surgeon. He adds, "Again, the diverticulum will be useless, as far as arresting air is concerned, unless it can be kept upright, or nearly so, throughout the operation." Notwithstanding his opinion, at every angle above the horizon, air, if present, is arrested by it. Mr. Jones argues that "it is impossible to predict that the receiver requires so many ounces, or that the donor can give so much." Quite so, but his deduction seems to be that therefore no advantage accrues from my transfuser measuring the quantity transmitted. Differing from him, I regard as highly convenient a record of the quantity of fluid injected. Again, he urges that in the cases "which the accoucheur and general practitioner most frequently have to face" the dynamic effect "is the sole effect which is desired." How then does it happen that the ever-to-be-praised "salino-alcoholic fluid" does not normally take the place of blood, if the oxygen carriers—the red corpuscles—perform a function of no significance?

Notwithstanding the many objections which Mr. Jennings, of the London Hospital, considers "inherent in blood transfusion," many successful cases are on record in which death was otherwise inevitable; and the lesson taught is that the two dangers attendant on the operation are the injection of air and the formation of coagula. The first I have overcome by the use of an air receiver; the second by preparing the blood of the donor before it is drawn from his vein. I have proved by repeated experiment that the administration of as large a dose of ammonia and of a saline as can well be tolerated, ten minutes before blood is allowed to flow, very conspicuously retards coagulation.

It is devoutly to be wished that the successes of the advocates of the syphon may be multiplied, and that therewith may dawn a consciousness of the fact that, although their treatment of the very distressing cases which point to this operation may be good, it does not by any means follow that it is either the only scientific one or the best.

I am, Sir, yours faithfully,

Meadowfield House, near Durham,

November 20th, 1882.

J. F. LE PAGE.

**M.B. London.**—An analysis of the candidates at the recent examination for the Bachelorship of Medicine shows that out of 52 who presented themselves for examination 41 passed, the rejections amounting to rather over 21 per cent. Of those who passed we find that 13 came from University College (and of these 8 were in the first division), 8 from St. Bartholomew's (2 in the first division), 7 from Guy's (all in the first division), 4 from Owens College (2 in the first division), 3 from King's College (1 in the first division), and 1 each from the Westminster, St. Mary's, St. Thomas's, Leeds, the Royal Free, and the London School of Medicine for Women. This was the first occasion on which ladies had presented themselves for a final medical examination. There were two lady candidates, who were both successful, one being in the first and the other in the second division.

**Dr. J. B. Gill.**—We have not heard of the decease of the person mentioned.

#### "INUNCTION IN SCARLATINA."

To the Editor of THE LANCET.

SIR,—Seeing that there is much controversy and difference of opinion at present carried on in your valuable journal on the above subject, will you allow an insertion of the following, which appeared in the *Gazette Hebdomadaire* of April 1st, 1859, written by M. Scoutetten, of Metz:—

"Many precautions have been adopted by physicians to prevent the unfortunate sequelæ of scarlatina and measles, and the confinement to the sick room for several weeks after convalescence ranks among them. I have adopted the following plan: As soon as convalescence commences, that is to say, when the skin is no longer red with the eruption, I rub over the whole body, slightly warmed, oil of sweet almonds or olive oil, and put the patient in bed again for two hours. The next day I give him a tepid bath for an hour, and then place him in bed, and if the skin is very dry a new friction with the oil is made. Those two frictions and one bath are usually enough to remove all danger; still, in severe cases, it is well, to avoid any risk, to repeat the means indicated from time to time, until the skin regains its suppleness. These precautions taken, convalescents may be permitted to go out without fear of bad results. In order to justify this method and explain its importance, it is necessary to remember the state of the skin in persons affected with measles or scarlatina. At the commencement of the disease the dermis is thick and swollen; during convalescence the tissues return to their normal condition, but the epidermis, which has been distended, not being elastic, becomes detached, and falls off in the shape of fine powder when the attack has been slight, and of large scales (desquamation) when it has been severe, and more especially is this noticed in scarlatina. The skin beneath is dry and harsh; perspiration and transpiration are badly performed, and the functions of this important organ are either impeded or suspended altogether for a time. When the skin acts badly, the kidneys and the mucous membranes of the air passages or of the digestive apparatus undertake to supply its place; thence arise a thickened sedimentous and often albuminous urine and severe diarrhoea, which generally terminate in emaciation and death; obstinate cough, sore-throat, croup, pneumonia, pleurisy with effusion; finally serous infiltrations into the areolar tissue of the limbs, and effusion into the various serous membranes. These severe symptoms occur after an exposure to cold of the skin, which inflammation has rendered more sensitive, and the functions of which are interfered with by an inert epidermis, which obstructs its pores. The object of the treatment proposed by M. Scoutetten is to oppose the causes of these symptoms."

I am, Sir, your obedient servant,

EDWARD A. BURGESS.

London, Nov. 28th, 1882.

To the Editor of THE LANCET.

SIR,—In reply to "Cutis" on the above subject, I would say that inunction in scarlatina is an old but efficient adjunct. I have for many years been in the habit of having my scarlet fever patients greased with pure lard from the commencement. It relieves the dryness and mitigates the great heat of the skin, and when the peeling commences it not only protects the denuded skin, but forms a nidus for the poison-laden scales, and prevents or retards the latter from causing further mischief. When this plan has been faithfully carried out I have seldom had any kidney trouble with my cases. In my opinion the neglect to oil, unless some precaution is taken during desquamation, produces renal trouble. The patient gets exposed with his denuded skin, and immediately the escape of the fever poison through the pores of the skin is checked, which consequently is directed to the kidneys in larger quantities than they can bear, giving rise to acute desquamative nephritis. The oil gives warmth and promotes the healthy action of the skin.

I am, Sir, yours faithfully,

H. ISAAC JONES, L.R.C.P., &c.

Scranton, Pa., U.S.A., Nov. 27th, 1882.

To the Editor of THE LANCET.

SIR,—Some years since (Jan. 7th, 1870) you permitted me to point out in your pages that restoration of skin action in febrile conditions was more completely and permanently effected by anointing than by the warm bath. How, then, can inunction, with consequent free skin action, have "a bad effect upon the kidneys?"

I am, Sir, yours faithfully,

H. G. KNAGGS.

Camden-road, N.W., Nov. 15th, 1882.

#### STRAMONIUM.

To the Editor of THE LANCET.

SIR,—In your issue of November 4th, page 744, a case is reported from the Bristol Royal Infirmary, under the care of Dr. Shingleton Smith, of poisoning by berries of stramonium (*datura stramonium* or thorn apple). In the first place, I would draw attention to the fact that *datura stramonium* has no berries. In the second place, that in poisoning by stramonium, dryness of throat is a common and persistent symptom. Even a small dose of tincture of stramonium will in some people occasion a very disagreeable dryness of the fauces.

I hoped some other reader of THE LANCET would have noted these errors, for, in the interest of toxicology, cases of this kind ought to be fully reported, both as to the real nature of the poison taken and the action of the antidotes employed, as in this case attention is drawn to the antagonism manifested by morphia to stramonium. I would also note the large dose of morphia injected—viz., one-sixth of a grain, the child being only seven years of age.

I am, Sir, yours faithfully,

Derby, Nov. 18th, 1882.

T. CARTER WIGG, M.D.

**Dr. Laffan.**—The communication forwarded is not sufficiently explicit as to the precise nature of the complaint.

#### TOBACCO-SMOKING: A HINT.

To the Editor of THE LANCET.

SIR,—I have only to-day seen your excellent article on the physiological effects of tobacco. Although accustomed to smoking for the last twenty years, I believe it has lately had a somewhat pernicious effect upon me; I, however, do not wish to give up my customary smoke, and for some time past I have smoked only cigarettes of my own make. I use the ingenious Connium machine, which enables one to use paper mouthpieces. Into the mouthpiece I insert a small plug of cotton-wool; the smoke being drawn through this filtering medium is, I think, almost entirely deprived of all noxious matter, and enters the mouth deliciously cool and not deprived of its aroma. I think if other smokers would try this method they would recommend it with advantage to some of their patients to whom the deprivation of tobacco would be a hardship.

I am, Sir, yours faithfully,

Bethel-street, Norwich, Nov. 17th, 1882.

H. TURNER, M.R.C.S.

**H. D.**—The subject is taught at nearly all the medical schools.

**A. X. G.**—We do not prescribe.

#### "PAINFUL MICTURITION."

To the Editor of THE LANCET.

SIR,—Your correspondent on the above subject has, I should infer from reading his letter, failed to make a careful and correct diagnosis in his case—the essence of successful treatment. It is possible, should the diagnosis be a villous tumour in the bladder, that great benefit may be secured to the patient by the following treatment. An injection of nitrate of silver, well diluted with lukewarm water, should be used twice a day, combined with the warm hip bath. I can testify to the success of this plan of procedure in a most formidable case of tumour of the bladder, concerning the nature of which there could be not the least doubt. Combined with this I should advise the internal administration of Fello's syrup of the hypophosphite of iron.

I am, Sir, yours very truly,

Bath, Nov. 28th, 1882.

M.R.C.S. ENG.

**Mr. Bradburn (Eccles).**—The full recipe was given in our last issue.

**M.D. (Tunbridge Wells)** has not enclosed his card.

#### HAZELINE IN PROLAPSEUS ANI.

To the Editor of THE LANCET.

SIR,—A widow lady, aged about forty years, has suffered for several years with prolapseus ani of a severe character, attended with frequent hæmorrhage. About a fortnight ago the bleeding was very profuse, so much so that wine and brandy had to be given to her frequently to keep life in her. All remedies had been tried by her medical attendant, Mr. Hutchings, of Southborough, and failed to arrest the hæmorrhage for any time. I wrote and advised them to try hazeline, and found it had just been tried with great success, all bleeding having stopped, and there has been no return of it. The patient is recovering.

I am, Sir, yours, &c.,

Lewes, Nov. 16th, 1882.

G. HOTHER, M.R.C.S.

An Australian Surgeon's letter is unavoidably held over till next week.

**Dr. H. Bruce (Edinburgh).**—Yes.

#### INSTITUTION FOR DUMB BOYS.

To the Editor of THE LANCET.

SIR,—I shall be obliged if any of your readers will inform me where there is a Protestant institution for dumb boys, and also let me know the charges, &c.

I am, Sir, yours truly,

Darwen, Nov. 27th, 1882.

BEARING ON

## ON THE PRESENT KNOWLEDGE OF FEVER.

A First Lecture.

By WALTER MOXON, M.D., F.R.C.P.,

PHYSICIAN TO, AND LECTURER ON THE PRINCIPLES AND PRACTICE OF MEDICINE AT, GUY'S HOSPITAL.

(Concluded from p. 333.)

NOW, with reference to fevers, I wish to draw your attention to the fact that we are able to be clear upon the idea of fever, both in the wider and the more restricted sense which I have just laid before you; and that in this relation of kind fevers differ from all other classes of diseases; at least this is the case of the contagious fevers, in which the disorder is propagated in a manner only comparable to descent by generation. Indeed, one of the most practical of the fruits of wisdom which experience will develop in you when you have seen much of professional work amongst families will be the earlier conclusion of the nature of an attack of illness by ascertaining the kind of fever to which a child has been exposed. And, again, it may be said that the chief evidence of the distinctness of kind among some of these contagious fevers has been obtained through most patient investigation and watching of local epidemic attacks of one fever or the other, in which it has been proved that each disease spreads in its own kind, and not in any other. This is the only conclusive argument to prove that typhus fever is distinct from typhoid fever; for all the differences which I shall have to detail to you as characterising typhus in its divergence from typhoid might be differences through accidents. I have seen a very crowded outburst of typhoid eruption amongst the rash in typhus, and *vice versa*. Ulcerated intestine might be a character superadded to some cases of typhus, as pneumonia is superadded to some cases of measles, or as diphtheritic disease to the fauces is fatally superadded to some cases of scarlatina. But when you find typhoid always breed typhoid, and typhus always breed typhus, then all question as to distinctness of kind ceases, or at least lapses into the more general question, whether species of fever can be constant when, as modern biology has shown or brought up to a general belief amongst all biologists, no species of any living thing either constant or ever has been constant. Not that this last reflection brings existing species nearer each other; for though they vary they do not vary towards each other, but always away from each other. They ever diverge; cats never varying to become dogs, nor dogs to become cats; so typhus never varies to become typhoid, nor typhoid to become typhus. This certainty of kind in fevers marks a vast difference in their nature and relations as compared with those diseases which I shall have to introduce before you when speaking of disorders of the lungs, heart, and brain. I shall then detail to you the characters of many things spoken of as kinds of diseases; but the word kind is much looser here, and indeed has only a quite vague and popular application. I remember being amused by a passage in some story. The author had got one of his characters into a hospital, and made a little poor fun in setting out the effect

said as how the thing what No. 3 has got in his head is the same as No. 6 has got in his stomach."

I suppose that the clinical teacher must have been asserting in the hearing of the author of this character that inflammation of the brain was of the same kind as inflammation of the peritoneum, and if the question was raised, Is meningitis the same thing as peritonitis? you would certainly see that meningitis differs from peritonitis, not like typhus and typhoid differ as generated kinds differ from each other, but meningitis and peritonitis would be always held to differ by differences untraceable in their nature, as the purple and white foxglove differ, so long as you considered them to be separated by the inalienable peculiarities of origin and relationship which separate the meninges from the peritoneal sac. But if you think that the physiologist and the pathologist could really set forth and explain all the differences between these membranes, then would peritonitis and meningitis differ in kind to you only when you used the word kind in a vague popular way, as when one might say that a knife is a different kind of a thing from scissors, or a pen from ink, in which case the phrase "different kind" means no more than that the differences are untraceable as regards the intents and purposes before you at the time. In short, popularly the word "kind" is applied to things in virtue of any likeness sufficient for the purposes of the occasion. This digression has been so long and our progress in the direct line so short, that you may scarcely remember that we digressed from the question, What are the general facts common to the several kinds of fever? into the question, What do you mean by a kind of fever? And now we must go back to the original question, and I must proceed to show you what those general facts are which are common to all fevers.

Stay though, we must have another digression, for I am afraid you might be content to regard every distinct kind of fever merely as a distinct sort of fever, and thus to ignore the relations of the several kinds of fever to one another. But if you take the facts of the several kinds of fever you will find that there are some of these facts special to each distinct kind, and others that are general to several of the kinds. And on perceiving and admitting this you must perforce regard the group of kinds of fever which have general facts amongst them, which facts are common to all of the group, but absent from all other kinds not included in the group. I say you must regard the group of kinds which have the common characters as in some sort genera of fever. And when you further find that some of the groups of kinds have facts common to such groups but absent from other groups, the groups thus connected must associate themselves into yet more general groups which become orders. So that, for example, Mr. Jones's fever has characters which bring it together with all cases of scarlatina, but amongst those scarlatinal characters is the fact of shorter duration, which makes scarlatina differ from continued fevers, but agree with a group including measles and small-pox, &c. But, again, amongst the characters common to all the group so included are some characters, such as the possession of a specific eruption, which bring Mr. Jones's scarlatina into association with the more continued fevers, typhus, typhoid, &c., but which separate it from all non-eruptive fevers. Mr. Jones thus becomes a case of the species scarlatina of the genus not continued of the order eruptive of the class contagious fevers, and thus you, as it were, perceive whereabouts Mr. Jones hangs upon the family

on the ignorant patients of the learned doctor's clinical remarks to his group of students. The impressions of the patient were rendered something in this way, "The doctor

tree of fevers, and you view his position with a greater total comprehension. Such a family tree view is a nosological view of fevers. You can construct such a tree as to

the family of fevers, but not as to other diseases. The nosology of other diseases is only an appendix of the anatomical and physiological arrangement of the several organs and parts of the body.

You will, I daresay, remember that all the while our question is, What are the general facts common to the several kinds of fevers? Well, now, you can see that we have reached a point from which we are at an advantage in solving that question. For when we have recognised what are the general facts that form the bonds of association of the several generations and families of fevers, then, as we have seen that these facts are themselves the principles of medicine with regard to fevers, we find that we thus reach at once our general principles, and can study them with due observance of their order of succession in importance. The facts common to the most inclusive group will be the most general facts and principles, and so on with less general facts to the less inclusive groups. Now, if you look at this scheme of fever, you observe that the most general division of fever is into primary and secondary fever. This is, indeed, not only the first in the order of nosology, but the first in practical application. In every case of fever that comes before you the first question is, Is it primary or secondary fever? One question only can precede this—namely, Is it a fever at all? What is fever? In its most general sense fever is still febris, fervid heat, and its only and sufficient criterion is heat. Not the feeling of heat. A patient may feel hot to you or to himself when he is really not so, and may be shivering with cold when he is thermometrically very hot, as in the cold stage of ague. But since the introduction of the clinical thermometer you can easily be quite sure of fever, or, as in this widest and most general sense it is more properly termed, pyrexia. You decide it by the thermometer. If his temperature is above 100° the patient has pyrexia. But in a vast proportion of cases pyrexia or feverishness is secondary to inflammation; and, in fact, before you pronounce a case to be fever you must be sure there is no local cause on which the pyrexia depends. Search for local inflammation. If there is no local inflammation, then it is fever, and it is called primary, or essential fever, or “fever” as distinguished from mere pyrexia. The next great characteristic, in which you find the first line of division of essential fevers is the character of contagiousness. This, too, is not merely first in order of generality, but in order of practical importance. When you are sure that the case is some kind of essential fever you will be asked by the friends, Is it contagious? A very serious consideration, on which depends the taking of immediate steps to ensure the safety of those around, steps which are annoying, troublesome, and costly, and which therefore must not heedlessly be enforced, but which are so imperative when necessary that there is no forgiveness if you fail to take them in due time.

And here I think it will be well to consider in a general way, and once for all, the great fact of contagion which is common to the more dreaded and deadly of the fevers. What do we know about contagion? Well, we seem on the very brink of knowing all about it, and yet we must perhaps on that very account be cautious. It is well to be circumspect on brinks. And the attitude of science is properly one of caution, especially of caution against the very probable. Science used to be always being misled by the probable. Therefore now let us challenge strictly all evidence when a general conclusion is to be drawn. The general conclusion is none other than that all contagious fevers arise through the entrance into the system of what are called “germs,” and that these germs are of the nature of living organisms, such as have from the first microscopical ages been known to microscopists as bacteria spirillum, micrococcus, &c. Many an hour have I spent in watching these, but never thought of associating them or any of their kind with fever; yet what I witnessed many years ago might have awoke a quicker perception to the anticipation of recent discoveries. I was watching floscularia, a stationary species of rotifer, resembling a relatively large bell with a Japanese quaintness of design about its figure. These creatures had come in large numbers in the aquarium at my dining-room window. Their textures are entirely transparent, and I was discovering their sense organs and the ganglion that represents their brain, and in particular I was watching the curious disappearance of a pair of bright-red eyes, which these creatures possess whilst they are young and active,—eyes which, like some other creatures, they lose when they grow old and acquire established positions. But, to my great sorrow, my floscularias, which had been thriving and multiplying freely, began

to die away before I could finish all the observations I had hoped to include in a paper which is in the Linnæan Society Transactions. As the creatures sickened they became turbid instead of clear; and whilst I was endeavouring to follow the nerves from the ganglia I saw that the obscurity which clouded them was due to the presence of countless bacteria, exactly such as I am now familiar with in Koch's figures. I now know that I was witnessing an epidemic of bacterium fever in a population of floscularias, but I was not seen enough to see what was before me then, as I looked for and thought only of nerves.

In 1873, Oberheimer of Berlin discovered spirillum in the blood of persons suffering from relapsing fever; and the fact that such organisms are in the blood in relapsing fever is beyond all question. This discovery might at first seem only a further extension of the knowledge we have of scabies through the finding of the itch insect. But there is this vital difference, that whilst the itch insect is living his quiet little life as an unwelcome guest, he creates no general disturbance except for some importunate sensations; whereas when spirillum gets into the system there is fever, and indeed intense fever. Evidently, then, the spirillum has a much more intimate and general relation with the system than the itch insect has, and it becomes a most interesting question what those relations really are. The facts are simple enough; indeed, are they not precisely such as science has long been aware of as occurring in the popularly well-known processes of vinous and acetous fermentation? In the fermentation and in the fever have we not definite systems of turbulent changes determined by the presence of living germs? Even before the discovery of the yeast plant fever was seen to resemble fermentation. Well, there we have a familiar and apparently close analogy to incline us to the view that relapsing fever, at least, is a colonisation by foreign living creatures which in some way breed a poison, or which, as some think, fill up and choke the life out of vital parts of the frame. This is a simple and plain view, and is easily accepted and understood. But the truth may not be so simple and plain, and I wish to draw your attention to an alternative view. This alternative view will appear to you if we ask the question, Are these spirilla—which, by the way, much resemble some spermatozooids—spermatic in any sense useful to recognise? Are they the offspring of the human body endowed with powers to disturb the vital processes of other human bodies? In a general way, there is a range wherein life and fever show enough in common to have been more than merely poetically or metaphorically parallel. For fever is like life in having its times of duration limited though uncertain, and in having its stages so that you can anticipate them, and you can recognise whether the fever is a young or an old fever; and, as our very question shows, fevers reproduce their kind. Here, then, are all the characters of a life: its uncertain yet sure limits; its stages of development; its power of reproducing itself. And so a fever might appear to be another life lived in and by its sufferer, and the human fevers would thus become, as it were, episodic lives supplementing human life; so that you have not quite lived until you have had your fevers; though it may be found for you that you have quite lived when in the middle of one of them.

There may be too much of some sorts of life. In strychnia poisoning or in laryngismus stridulus, for instance, the convulsions themselves cause death. But convulsion is itself an act of life, and so you may die by too much life. Life is a paradox, look at it as you will. You know that from the chemist's point of view life ought to settle itself at once by the several elements obtaining their favourite affinities, and being forthwith satisfied, which they never do until life is over. Life is such a paradox. But from my present point of view life itself is, as it were, a protracted infection of the germ by the sperm, and the living body remains during its life germinal to other infections when suitable spermatic elements come in contact. If this view seems to you more fanciful and supported by less analogy than the fermentation theory, I will at once put before you what is a serious difficulty in accepting the fermentation theory of fever. On this theory is it not very difficult to explain how it comes to pass that one attack of a contagious fever protects from the danger of that fever ever after? This, as we shall subsequently see, is not strictly true, but it is generally true. If fever is merely colonisation with germs who feed upon and live in the body, why should they not come and feed and live again? The only explanation I remember to have seen offered is that the unsophisticated human frame is born

with a small amount of some very special food of which the fever germs are very fond, and it is supposed that these little organisms are so fastidious, that they will not take any other nourishment, so that when they have consumed the whole supply of this kind of food, they die or depart to other feeding-grounds. Now, seeing that according to biological science these germs are only protoplasm, it would be very surprising if it turned out to be true that minute unspecialised organisms such as swarm in every puddle where organic decay is progressing should refuse to accept any nutriment other than some inborn kind of delicacy; and when you reflect that there must be a number of these delicacies, for no fever germs will pasture on the food of others, and in fact the ambrosia of one is caviare to the rest, it puts no little strain on the highest genius for imaginative scientific belief to suppose that we are all sent into the world each to bear a little special supply for the several kinds of fever germs to thrive upon.

On what seemed to you perhaps the more fanciful view we may suppose that the human frame can cast off spermatic elements which when they enter other human frames engage in an activity remotely like that which originates germination, so that for awhile, if I may so speak, the protracted germination which constitutes life is itself reinfected and diverted. We may suppose that this activity constitutes the fever; and that when once the fever is over and its life lived, it does not return. Were this really the case, would you not expect that these episodic lives would be most probably lived during the actively growing germinal years of earlier existence, or, in other words, would not the fevers attack children? Which indeed they do. Again, if you suppose the immunity from subsequent attacks which fever affords to be due to exhaustion of materials suitable to the parasitic germs, how can you explain those rather frequent cases in which typhoid fever or measles repeats its attack upon the convalescent patient, and even recurs a third time after defervescence? For if you suppose the immunity to be due to exhaustion of a material suitable to the parasitic germs, how can you explain the reappearance of the fever, and therefore of the germs with their supplies, just after the cessation of the first typhoid attack has shown that all supplies were exhausted? But if you concede that this proves the immunity in question not to be due to such exhaustion of supply, then how do you at all explain that subsequent immunity which is so marked and so happy a feature in the history of contagious diseases?

Well, then, the recurrence of typhoid fever cannot be a question of food of the germs. And if not, we must suppose that the repetition which makes three typhoids is due to some measure of time in the life of the typhoid germs themselves, so that each brood lives just the time of one attack, and the next attack is due to other broods whose life has a time limit equal to that of the fever. But these germs are minute unspecialised particles, which reach their little perfection with extreme rapidity, and all that is known of their rate of growth is the reverse of conformable to periods of fever measured by weeks.

On the other hand, if we suppose the fever process to be an episodic vital action between the elements of texture of different individuals, there is nothing contradictory in supposing such vital actions to be sometimes lived through a second or even a third time. Not long ago at the Pathological Society, there was under debate a question how we should explain the late manifestations of so-called tertiary syphilis and the syphilitisation of the fetus whose mothers, having passed through the disorder, are not then actively diseased. And I endeavoured to show that these and similar facts are explicable by assuming that tissue of recent origin, or tissue by chance left unsyphilitised during the syphilitic fever, undergoes impregnation with the syphilis germs which chance to come from habituated older parts of the frame into contact with the new tissue, either through such an intercommunication of the several parts of the frame as is supposed in Darwin's theory of paragenesis, or, else, in the more easily understood instance of the syphilitic fetus, through the blood of the mother. And I pointed out that the observations of Mr. Tomes on the Haversian spaces of bones, proving that fresh texture arises and replaces old texture in the life of adult bones; that these observations make it probable that similar new formation occurs in other textures, giving rise to new-formed tissue, which would be germinal to or capable of vitally receiving any poison which might be transmitted to it from the already syphilitised general textures. If this is true, though I now cannot give you all the evi-

dence in favour of such a view, then, in tertiary syphilis we have occurring within the body of one and the same individual an infection of young and virgin tissue by a poisonous effects of older tissues charged with a cause of infection to which those older tissues are themselves longer susceptible. Such a fact would form a step towards the admission of a like infection by the tissues of a habituated individual of the tissues of another not habituated.

But I have hitherto overlooked a branch of evidence of the existence of which you must be duly apprised. Though I may be allowed to deal judicially with the facts as offered, and facts are offered by the most accredited observers which would go to prove that the germs of a fever to which mice are subject can be grown into a fungus which produces spores, and that the spores of this fungus will reproduce the fever in other mice, whilst the fungus threads do so unless spores be present. Such researches are, of course, very elaborate, and when admiring the thoroughness and continuity of the work, and the skill and insight displayed in the views of the experimenters, I must recognise also the extreme difficulties in avoiding fallacy, and the corresponding possibility that fallacy was not avoided; for to obtain the germs of fever about 10,000th or 20,000th of an inch large, and to plant them and grow them to a fungus, you must be able to follow the individuality; nay, you should never, if possible, lose sight of the individuals. It would be well to identify these germs and, indeed, it would be much more secure if they could be marked—say, for instance, by tying little bits of blue ribbon upon them to distinguish them from the infinitude of vulgar multitudes of other germs everywhere around them. And it might be said that these germs did deserve such a token of distinction on account of the sober way in which they behave exactly according to what the commanders in the experiment expected of them. Indeed, if you will trail a little poetry amongst bacteria, they are so numerous and so light that they will gather around and give body enough to the form of your conception so as to make good your theory and set it going in living shape; and a biological theory will have a very happy life when enclosed in a body of active germinal infective protoplasm. It is, indeed, the most fashionable creation of the period. But one must not speak irreverently of protoplasm, and our subject is all the more serious. The question may appear a very narrow one when we ask whether fever germs are independent parasitic organisms on the one hand, or specialised parts belonging to the human species originally taking their life from the human body. But to be stuffed with foreign germs is really so very different a thing from having your texture life set into new vital action by spermatic particles from the texture of another person, that it would be well to know which is the truth, if we can only find it out. As to the coarser view which has been advanced, to the effect that the mechanical action of fermentation germs may cause the phenomena and fatality of fever, we are not without an instance to show us what really are the consequences of the presence in immense numbers of micro-organisms in the human blood. The recent discoveries concerning *filaria sanguinis hominis* show that the minute worms may exist in myriads and circulate in the blood without producing any fever, and, indeed, without causing any grave symptoms, and this, when these worms are so numerous as to be immediately found in every drop of blood examined. Indeed, the history of *filaria sanguinis hominis* seems almost to give a crucial negative to any theory which would suppose fever to arise from a mechanical action of germs—that is, through mechanical destruction produced by the germs. For when we thus speak of fever germs as perhaps always present in the blood, we must not suppose that one only has to get a microscope, a slide and put a little fever blood under it to find it full of germs. No, try in any of our cases of typhoid in the way and you will find these germs by no means very easily covered or obvious things. At the outset of such an inquiry you must take notice that the blood serum is often crowded with minute particles which must not be confounded with bacteria, and which exist often to a large extent in the blood of healthy persons. During last winter clinical session I was one of my most acute and intelligent friends, perhaps now absent, sent, searched carefully for germs in the blood of severe typhoid cases. The result was that one bacterium was seen, only one, but I was told it was a very active one. When I say that Mr. Booth saw it, you will know it.

well seen, for we all regard Mr. Booth as one of the very ablest and very best students at Guy's, but perhaps the main fact was that all were quite sure that there was only one bacterium. Next lecture we will take up in detail the consideration of the history of contagion.

## A CASE OF ULCERATIVE ENDOCARDITIS WITH PYÆMIC SYMPTOMS.

BY JULIUS POLLOCK, M.D.,  
PHYSICIAN TO CHARING-CROSS HOSPITAL.

ATTENTION has lately been drawn by Dr. Sidney Coupland, Dr. Wilks, and others, to a rare and interesting form of ulcerative endocarditis with pyæmic symptoms. In most, if not all, of the cases there has been old valvular mischief of the heart, upon which the fresh ulceration has been grafted, and some importance has been attached to the presence of former cardiac mischief. In the following case the symptoms came on during the course of a first attack of rheumatic fever, the heart being quite sound; and it has this further interest, that the case is absolutely complete, having been under observation from the first appearance of the rheumatic fever until the closing scene. I am indebted to Mr. C. A. Wigan, resident medical officer, for the carefully prepared notes of the case.

M. J.—, aged twenty-two, a single woman, was admitted into Charing-cross Hospital, under the care of Dr. Pollock, on Sept. 7th, 1882, suffering from a first attack of acute rheumatism. On admission she complained of pain in both knees and ankles and in the shoulder of the left arm. She also had some pain and stiffness in the joints of the right hand. Temperature 101.2°; pulse 84; heart normal, with no irregu-

loss of power in the left shoulder. On the 5th the joints in both legs became painful and swollen, so a doctor was sent for, who recommended her to go into a hospital, and accordingly she was admitted into Charing-cross Hospital on Sept. 7th.

Her temperature on admission was 101.2°, and the pulse 84. There was the usual sour-smelling sweat, and the urine was high-coloured and acid, but otherwise normal. The heart was carefully examined, and found to be normal. As the bowels were confined, she was ordered ten grains of colocynth and calomel pill for that night, and the following mixture: Salicylate of soda, fifteen grains; carbonate of ammonia, four grains; decoction of cinchona, one ounce, every six hours. A chart of the temperature, taken every four hours, was started.—Sept. 3rd: No change in temperature. The urine contained no albumen, but was found to be very acid, and thirty grains of bicarbonate of potash and three grains of iodide of potash were added to the mixture. Pills repeated. The patient shortly lost all pain in the right arm, both knees, and ankles, but suffered much in her left shoulder and arm, the slightest movement causing great pain. Pulse about 90; heart normal.—28th: Patient still complains of great pain in the left arm, especially in the muscles of the upper part. The temperature at 6 P.M. was 102.8°, consequently the old mixture was discontinued, and the following ordered:—Sulphate of quinine, two grains; carbonate of ammonia, two grains; bicarbonate of potash, twenty grains; chloroform water, two drachms; to one ounce of water: to be taken three times a day. This seemed to have a very beneficial effect, as the temperature fell to normal, and remained so until the morning of October 2nd, when at 9 A.M., without any apparent cause, she was seized with a severe rigor, lasting fifteen minutes, and followed by a profuse sweat. The temperature ran up from 98° to 102.4°, but fell at 2 P.M. to 100.6°; rising again to 102.6° at 6 P.M.—3rd: The temperature at 2 P.M. was 98°, but another rigor, as severe as before, occurred at 12 P.M., the temperature

larity nor bruit. From her previous history she appears to have had measles when an infant, but no other serious complaint. Her father died of pleurisy (double) aged forty-four; had always been a healthy man. Her mother is still alive and healthy. Three brothers and five sisters alive and healthy; four died quite young. The patient states that on Sept. 3rd, the day before she felt ill, she had a hot bath and went out for a walk directly afterwards in the rain, and got wet through. The same night she felt chilly and sick, and vomited shortly after getting into bed a greenish fluid with a bitter taste. Patient got no rest during the night, owing to the feeling of sickness, which continued. The next day (Sept. 4th) she got up. She did not complain of any chilliness or fever, but felt some stiffness and experienced

rising to 103°.—4th: Another rigor at 6 P.M.; temperature 104.4°.—6th: Another rigor at 9 A.M.; temperature 102.8°. The rigors were followed by a profuse sweat in a quarter of an hour. Up to this date the heart-sounds had been normal, and excepting some increase at the time of the rigors, the pulse-rate had varied from 76 to 96 per minute; but on the morning of the 6th a very soft and indistinct whiff was heard with the first sound at the apex of the heart. This gradually developed, until, on the morning of the 12th, a characteristic murmur was plainly heard at the apex with the first sound, and was gradually lost when traced into the axilla.—14th: Three grains of the sulphate of quinine were given in milk three times a day, and four ounces of brandy per diem.—16th: The murmur is now very dis-

t, and is rasping in character. It can be heard all over chest. A very wide range of temperature was noted—104° at 2 A.M., 97° at 6 A.M., 104° at 2 P.M., and 101° at 3 P.M.—17th: Up to this date the breathing has been good, and not much increased in rate; but to-day she had a short and irritating cough. Respiratory murmur sh, no dulness on percussion, slight amount of sputum. Pulse was quickened considerably, being 138 in the morning and 132 in the evening.—18th: The variations of temperature are not so severe; it now ranges between 100° and 103°; pulse still 138. Cough harder, sputa more abundant, and rather rusty. Respiratory murmur harsher; apnoea at times. She complains of loss of appetite and a feeling of sickness, and has not slept for two nights. Ordered solution of hydrochlorate of morphia, five minims; nitrate of bismuth, ten grains; bicarbonate of soda, ten grains; compound tragacanth powder, ten grains; one ounce of water: to be taken at bedtime. This had a good effect, and she slept for five hours.—19th: Dyspnoea has a good deal increased. The cough is irritable; sputum very rusty, almost red, but with a greenish-purple tinge and there. Some dulness and bronchial breathing over both bases. Pulse 138 in the morning and 150 in the evening. The cardiac bruit is very loud and harsh. Brandy creased to eight ounces.—20th: Dyspnoea very marked. Pulse 138. Dulness on percussion most distinct over the middle of the left lower lobe. Temperature 103.6°.—21st: Breathing very laboured; respiration 56. Very small expectoration over the left lower lobe; coarse râles over the right base. Temperature 101°; pulse 138, very feeble, and evidently failing. Sputa free in quantity, of a dark-prune colour. Very small amount of urine passed; sp. gr. 1021, and a trace of albumen for the first time.—22nd: At 2 A.M. the patient was comatose, the pulse being just perceptible. Death took place quietly two hours later.

*Necropsy, thirty-four hours after death.*—The body was well nourished; some rigor mortis still present, and no external appearances of disease. On opening the chest, the left side was found to be full of fluid; there was also some, but less, in the right. The left lung was indurated about its middle third, and the upper part of the lower lobe was of a dark prune colour, with granular consolidation, and readily broken down. There were evidently two or three infarctions of recent date. The rest of the lung contained a small amount of serum, but was otherwise healthy. The right lung was the seat of four or five indurated patches, the result of pyæmic pneumonia, and also contained some serum. The heart weighed nine ounces and a half. The wall of the left ventricle was somewhat thickened, and there was recent ulceration on the right border of the mitral valve, and around it some exuberant vegetations, soft and easily detached. These were continuous for nearly an inch along the right border of the valve. No atheroma, no other valvular mischief. The liver was normal, weight fifty-one ounces. The spleen normal, weight eight ounces and a half. The kidneys weighed nine ounces and a half. Their capsules were slightly adherent, and the pyramids congested, otherwise healthy. Brain normal, weight forty ounces.

*Remarks.*—Ulcerative endocarditis with pyæmic symptoms must be very rare. I have watched with much interest the course of a large number of cases of acute rheumatism, many of which were accompanied by valvular cardiac disease, but the above case is the first of its kind that I have come across. What is it that determines the pyæmic symptoms? Presumably the presence in the blood of minute organisms—microzymes; but how they get there is as yet unexplained. As Dr. Burdon-Sanderson has pointed out,<sup>1</sup> it is necessary for the production of infective disease that there should be present at the same time inflammation and bacteria; either may exist alone, but no pyæmic symptoms result. In the foregoing case the absence of all trace of metastatic abscesses in the liver, spleen, and kidneys is rather remarkable. The chief evidence of the existence of pyæmic dissemination was found in the lungs, and during life the sputa were very characteristic. The treatment of ulcerative endocarditis with pyæmia is most unsatisfactory. None of the ordinary remedies had any real effect, nor did large doses of alcohol sensibly improve matters. I wish now that I had tried the inhalation of carbolic acid, or the carbolate of iodine, and I would suggest giving such a line of treatment a fair trial in any cases of the kind, especially where the lungs appear to be much affected.

Harley-street, W.

## REMARKS UPON THE OSSEOUS LESIONS OF LOCOMOTOR ATAXY,

WITH A CASE SIMULATING MALIGNANT DISEASE.

By J. ALEX. WILLIAMS, M.B., M.R.C.S.,

HOUSE-SURGEON TO THE ROYAL PORTSMOUTH HOSPITAL, LATE HOUSE-PHYSICIAN TO THE LONDON HOSPITAL.

THE conspicuous absence from our museum, previous to the researches of Charcot, of specimens illustrating the osseous and articular lesions of locomotor ataxy, induced Sir James Paget<sup>1</sup> during the meeting of the late International Congress to ask Professor Charcot, "Whether these are not instances of a disease which has lately for the first time appeared, or at least has lately become much more frequent than formerly it was?" Now with all due deference to so great an authority, I cannot but think that their more frequent recognition in modern times is mainly owing to the increased facilities afforded us for the diagnosis of the disease in its early or pre-ataxic stage, and this is chiefly due to the labours of Duchenne, Westphal, Erb, Hutchinson, Jackson, Charcot, Buzzard, Robertson, and many others. For Professor Erb<sup>2</sup> writes, "this arthropathy is most common in the early stages of tabes, and chiefly in the preliminary period before the ataxic disturbances of motion have appeared, and when the lancinating pains constitute the chief feature of the complaint," and this assertion I believe holds good for the osseous lesions. Hence it is highly probable before the diagnostic significance of "lightning pains," ocular pareis, and Westphal's symptom were known, that many cases presenting tabetic arthropathies, or osseous lesions, were diagnosed as examples of rheumatoid arthritis, or of malignant disease of bone, &c., as might easily have been done in the case now recorded. The frequency with which patients describe their pains as "rheumatic" is strong presumption in favour of this view. Dr. Hughlings-Jackson,<sup>3</sup> referring to a case of tabes whose only symptom besides lightning pains was the Argyll-Robertson pupil, says "the case might be taken for one of neuralgia only by those who have not studied lightning pains, and who do not examine the pupils." Dr. Buzzard in a foot-note to his paper<sup>4</sup> upon the subject, says, referring to the arthropathies, "In most of those which I have published, the nature of the underlying disease had never been suspected." He instances a case in which excision of the knee-joint was very nearly performed in a surgical ward of a hospital; also of two other patients, inmates of surgical wards, who had been exhibited to candidates at an examination for a diploma as examples of rheumatoid arthritis. Charcot, in answer to a remark of this same authority, complaining of their rarity in England, said, "You will find them in the workhouse infirmaries, and in the surgical wards of hospitals." How true this remark was recorded cases testify.

In addition to the case I am about to record, in which, although the tabetic symptoms were recognised, a diagnosis of malignant disease was nearly completed and operative procedures almost resorted to, I can remember the case of a middle-aged man who came under my observation for incontinence of urine, at a time when I was house-physician to Dr. Gilbert Smith at the London Hospital, under whose care he was admitted. Here none of the ordinary causes of incontinence could be found, but the right hip-joint was much enlarged and disorganised by large irregular bony outgrowths, which also projected into the pelvis. The patient, a dull stupid man, had never before noticed the enlargement around the joint, but he walked lame with that foot. On inquiry into his history it was found that his lameness dated from an injury received some six or seven years previously, in which he said his hip had been dislocated by its entanglement in a cart wheel. Further inquiries elicited the fact that he was the subject of marked ataxic symptoms; thus he had been subject for many years to sciatica, his pupils presented the Argyll-Robertson phenomenon, and there was a total absence of knee-jerk in both knees. He walked with the

<sup>4</sup> On the Affection of Bones and Joints in Locomotor Ataxy, &c., Brit. Med. Jour., March 5th, 1881.

aid of a stick, and had a somewhat ataxic strut, which, however, might have been due to his lameness. The eyesight was not affected, and so far as I remember the optic discs were normal. There had been no gastric crises. He was seen by Dr. Jackson and Mr. Hutchinson, both of whom confirmed Dr. Smith's diagnosis of ataxy, and considered the osseous material surrounding the joint to be unabsorbed callus, produced in excess in an ataxic patient, as a result of previous injury to the femur close to its neck. Now, such a case, in the event of the pain not having been inquired after, and the eye and knee phenomena not tested, might readily have passed for a severe example of rheumatic arthritis, or even of malignant disease of the bone.

From the analogy which these trophic changes in bones and joints present to the arrest of the growth of bones often observed in infantile paralysis, they have been assumed by Charcot to be due to implication of the anterior cornua of the grey matter in the sclerotic process. Buzzard, on the other hand, having observed gastric crises to be more frequent in these cases, has suggested sclerosal invasion of the roots of the vagus nerve as the cause of the altered nutrition in the osseous system. Neither of these theories, however, has been satisfactorily borne out by anatomical observations, and it is to be noted that in neither of the cases here referred to were gastric crises observed. Charcot, when demonstrating the arthropathies upon the wax model of Berthelot, before the late International Medical Congress, remarked<sup>6</sup> that "fracture of the bones and diseases of the joints appear to belong to the same pathological condition—i. e., when the disease attacks the diaphyses of the bone, the atrophy is proved by fracture; when it attacks the joints, we get the wasting of the head of the bone with erosion of the surface." In this case nearly all the larger articulations were affected, and there was an excessive production of callus around an old fracture of the right pelvic bone upon its inner surface. In the main these arthropathies are characterised by a rapid and sudden effusion of serous fluid into a joint, the knee most frequently, usually unattended by inflammatory symptoms, but followed by rapid erosion and absorption of the articular extremities, with relaxation or destruction of ligaments; the joint becomes flail-like, and dislocations readily occur. Such a condition might readily be mistaken for a simple hydrops articuli were the ataxic symptoms neglected. The swelling is never entirely confined to the joint itself, but is diffuse and often extends over the entire extremity, and large osseous outgrowths often occur around implicated joints. The rapidity with which these changes are produced in ataxy is peculiar, a few days sometimes sufficing for the complete destruction of a joint (Buzzard). Osseous lesions often coexist with arthropathies, and *vice versa*. They are characterised by abnormal brittleness of bone, due to a rarefying osteitis, whereby the Haversian canals become abnormally widened at the expense of the osseous matrix—as a result spontaneous fractures from the slightest movements, such as turning in bed, &c., are of frequent occurrence. These fractures seem to possess great reparative power, and "it is common to find a more than usually exuberant callus thrown out" (Buzzard). This statement is typically illustrated by the following case, in which from slight muscular exertion the right femur became spontaneously fractured, rapidly followed by an excessive production of callus, causing great swelling of the affected thigh, and in its clinical aspects closely simulating malignant disease.

Philip H—, aged forty, street musician, was readmitted into the Royal Portsmouth Hospital on July 2nd, 1882, under the care of Mr. Rundle, with a fracture of the right femur. He gave the following account of his accident:—On April 23rd, when taking off his boot, he crossed the right leg over the left knee, but meeting with some difficulty in pulling at the boot, he gave the leg "an ugly strain," producing what on admission, the same evening, proved to be a transverse fracture of the right femur at the junction of its middle and lower thirds. The fracture was treated with plaster-of-Paris splint encasing the foot, thigh, and pelvis, and thus far successfully that on June 18th there was good bony union, and he was discharged cured, the leg for a short distance above and below the site of fracture being encased in a short plaster-of-Paris splint. No excess of callus was then observed. When at home, he said everything progressed satisfactorily, and, with the exception of slight pain beneath the splint, he had nothing to complain of. In about a week he discontinued

the use of the splint, but remained cautious in his movements upon crutches. On July 1st, in walking across his room, he incautiously placed his body weight upon the injured leg, and immediately felt it give way beneath him. Next day, when brought to the hospital, he was found to have refractured his right femur at the seat of the former lesion. Next morning (July 3rd) the limb was observed to be much swollen, and very painful. In its lower two-thirds the femur appeared immensely thickened, by a hard and osseous-feeling material, which below terminated abruptly at the knee-joint, posteriorly the popliteal space was almost entirely filled by a similar material; above the thickening gradually terminated so that the upper third of the femur felt normal. The superficial veins of the thigh were very conspicuous; but the inguinal glands were not enlarged. Circumferential measurements of the thighs in different positions showed a great increase in the size of the right thigh, thus:—

	Just above knee.	Middle of shaft.	Level of groin.
Left thigh, 12 in.	..... 15½ in.	..... 19 in.	
Right " 16 "	..... 18½ "	..... 19½ "	

On inquiry into the general history of the patient the following was ascertained:—He had formerly been a cork-cutter by trade, but for the last six years has been blind, and has since earned his living by playing the concertina. When seven years of age a "terrible" tumour was removed from over the right inner malleolus, the scar of which is still visible. When fourteen years old he had a bubo in the right groin. He denied syphilis, but in addition to the scar in the groin he has numerous coppery scars on both shins and spots on the chest, and, besides, presented well-marked ataxic symptoms. Thus: he has been subject to sciatica for the last seven years. His eyesight failed him six years ago; it commenced as dimness of sight, which gradually got worse, so that he is now totally blind, even to the discernment of light. During the last two years he has walked badly; "staggers slightly," this he attributed to his blindness. When in hospital it was observed that the pupils were unequal, the left being about the size of a No. 9, the right about the size of a No. 6 catheter on the English gauge. They presented the Argyll-Robertson phenomena—inactive to light, active during accommodation. There was well-marked white atrophy of both optic discs, and an entire absence of knee-jerk in the left knee; that in the right could not be tested on account of the fracture. There were no gastric crises. On account of the condition of the limb, malignant disease of the bone being suspected, no further treatment than placing the legs between sand bags was deemed necessary. It subsequently increased still further in size, and on July 5th attained its maximum measurements of: above the knee, 17½ in.; middle of shaft, 19½ in.; level of groin, 20 in. On July 17th, iodide of potassium was prescribed internally, and oleate of mercuryunctions applied locally. The limb, then, contrary to expectation, decreased gradually in size, and firm osseous union between the fractured ends resulted, so that on Sept. 23rd he was again discharged cured. At this time the limb measured: above the knee, 15 in.; middle of shaft, 17½ in.; level of groin, 19 in. There was still a large amount of unabsorbed callus surrounding the femur, most evident at the site of fracture and in the popliteal space. As a precaution, the limb was encased from the toes upwards in a stout plaster-of-Paris splint, and the patient warned to be very cautious in his movements and to use crutches.—Oct. 27th: Visited the patient at his home. He walks with aid of a stick, and has discontinued the use of a splint for two weeks past. The right knee, he says, feels very weak, and the ligaments are somewhat relaxed. Both knees present Westphal's symptom. The swelling of thigh has slightly decreased since last observation; it now measures: above the knee, 14½ in.; middle of shaft, 16 in.; level of groin, 19 in. There is still great excess of callus around lower two-thirds of femur, the upper third still being free. No glandular enlargements. The right foot has become cedematous during the last month, probably due to pressure upon the veins by the callus. The other symptoms are unaltered, and the fracture is firmly united.

Remarks.—This case affords a good illustration of most of the points previously referred to in the paper. The difficulties attending a correct diagnosis were such that at one time a consultation of the hospital staff was held to consider the advisability of amputation for malignant disease. Recognising, however, the difficulties attending the case in the absence of cachexia, glandular enlargements, and signs of

<sup>6</sup> Transactions, vol. 1, p. 128.

secondary deposits it was thought best to watch its progress for a short period before resorting to operative procedure. The wisdom of this decision was subsequently proved by the slow but steady decrease in the swelling, and the unexpected repair of the fracture. The changes, in fact, so far as the illness was concerned, were regressive and reparative, not progressive and destructive, as in carcinoma, &c. It will be served that the ataxic symptoms present were those which only belong to the pre-ataxic stage and were such that the ocular and Westphal's symptoms been neglected the injury must have remained undiagnosed. Another noteworthy feature was the rapidity with which the callus was grown out, for immediately after the second fracture when refully examined by Mr. Claremont, the surgeon to the hospital, no abnormal excess of callus or osseous material was observed. Yet forty-eight hours afterwards (July 3rd) when I first examined him there was then found very excessive formation of callus as recorded in the notes. This fact becomes of special interest when we consider Buzzard's statement, previously referred to, regarding the rapidity with which the joints are sometimes destroyed in these cases.

For permission to record this case I am indebted to Mr. Temple, under whose care he was admitted, and for many of the notes to my friend Mr. Cooke, the dresser to the case. Portsmouth.

## OIL OF TURPENTINE IN EGYPTIAN ENDEMIC HÆMATURIA (BILHARZIA HÆMATOBIA).

By JOHN WORTABET, M.D.,

PHYSICIAN TO THE HOSPITAL OF THE KNIGHTS OF ST. JOHN, BEYROUT, SYRIA.

MY attention was first drawn to endemic hæmaturia about five years ago. Since that date I had seen six cases, three of which I had under close observation for some time in the hospital, affording me a good opportunity of studying the disease and trying different methods of treatment. I am allowed to give the results of this study with the hope that they may be useful to the surgeons of the British army now in Egypt, where they may have occasion to see and treat the disease. I shall first give the notes of my last case, in which the oil of turpentine produced a complete cure, and then give some remarks on the general nature of endemic hæmaturia and its parasitic origin.

B. M.—, a well-made young man, aged twenty years, a native of Egypt. He was admitted into the hospital on June 2nd, 1882, and gave the following history of his case:—When he was twelve years of age he began to feel pain in voiding his urine, and wetted the bed every night. Four years ago he observed a small quantity of blood passing with his urine, or soon after it, and always with some pain. After he had passed water about seven or eight times a day. At night he invariably had incontinence of urine and unconsciously wetted the bed. His strength was fair, but he was not able to sustain much or long-continued physical exertion. On his admission there was only a slight trace of anemia, and with the exception of his urinary trouble he complained of nothing else. During his stay in the hospital his urine was examined frequently, often daily, and with the blood, ova and free embryos of the bilharzia were at all times always and plentifully found. In other respects the urine was not much changed from the normal state. Soon after his admission he was prescribed large doses of quinine, taking the first day sixty grains, and forty grains on each subsequent day for five days. But there was no change in any of the symptoms, and the blood passed was as full of ova and living embryos as before.

On June 14th I ordered a teaspoonful of oil of turpentine with a little milk three times a day, and this treatment was continued to July 8th. The blood was examined almost daily, and I was gratified to observe that in a few days it presented only broken ova and what appeared to be the debris of dead embryos. On the 25th the blood ceased, the nocturnal incontinence of urine stopped, the strangury was less, and the calls for micturition were diminished.

On July 8th he seemed to be perfectly cured. There was no blood, no ova in the urine, no strangury, and no incontinence, but there was still abnormal frequency of voiding

his urine. At this date the oil of turpentine was stopped. He had taken it for a little more than three weeks. He was retained another week in the hospital for further observation, and was dismissed on the 13th. I saw him again about six weeks afterwards, and he reported himself perfectly well, with the exception of a slight pain in passing his water. I examined his urine, and found it quite normal.

*Remarks.*—Though endemic hæmaturia has been long recognised as a distinct variety of bloody urine, its true nature and connexion with the parasite was discovered in 1851 by Bilharz, a professor of anatomy in the Egyptian Medical School, who, with Griesinger, found the worm in the portal, mesenteric, and vesical veins, thus accounting for the presence of its ova in the urine. Dr. John Harley and others saw and described a number of cases from the Cape of Good Hope; and Dr. William Roberts says that the disease has been identified in the Mauritius and Brazil. To this geographical distribution I can add Syria, at least the town of Jaffa, from which place I have seen one unmistakable case, and have heard of others there; but this is the only Syrian case I met, though I have carefully watched for the disease. Bilharz and Griesinger found the parasite in 117 cases of autopsy out of 363; and they believed that probably more than half of the native inhabitants of Egypt were victims of this disease. Sonsino found it in thirty cases out of fifty-four; and he believes that nearly all the natives of Egypt have it. The symptoms of the disease are few and simple, but well marked. The patient complains of passing a small quantity of blood, varying from a few drops to a teaspoonful, just at the end of making water, with a little pain, which continues for a short time afterwards. The frequency of micturition varies from half a dozen times to a dozen. There is always more or less anemia and a sense of weakness after any ordinary exertion. The quantity and specific gravity of the urine are natural, but there is always blood, more or less of albumen, and an abnormal deposit of mucus. In bad cases the reaction is alkaline, and the sediment shows a number of crystals of triple phosphates, indicating some degree of chronic cystitis, for which the disease may be easily mistaken. The chief point of interest in examining the urine is the ova of the bilharzia, which are found in large numbers entangled in the clots, though they may be often seen free among the blood corpuscles. They may be detected by a low power, and can be afterwards examined with one moderately high. They are about  $\frac{1}{10}$  of an inch long, quite ovoid in form, with a spike at one extremity, and once seen cannot be easily forgotten. When the ovum is carefully examined with a magnifying power of 250 or 300 diameters, the embryo is seen within it, having a distinct border of its own lying close to the egg-shell, except at the two extremities. In some of the ova, which appear to be in a more advanced state of maturity, but not in size, the embryo may be seen to expand and retract itself, probably in a fluid which lies between it and the egg-shell. Dr. Harley hatched the eggs by immersing them in water. A more expeditious way is to crush the egg and liberate the embryo by gently pressing the two glasses. This can be done while the eye watches the process from above, and it is interesting to see the egg broken and the living embryo emerging from the shell, and its cilia put at once into vigorous motion. Not unfrequently free embryos may be seen with their broken shells among the blood-cells, occasionally, in very fresh specimens, racing across the field with incredible velocity. The form of the embryo is also ovoid, not much larger than the egg, having a somewhat pointed extremity, which appears to be the head or mouth; and projecting from its sides from one end to the other are innumerable fine cilia, which appear to be always in motion, though the animalcule does not change its relative position. It is supposed that the embryo must undergo more than one transitional stage before it assumes its ultimate shape of the adult worm. The worm, which never comes out with the urine, is described by Bilharz as a filiform body measuring from three to four lines in length. The male is thicker than the female, and has a long canal into which the female is received during copulation. It inhabits the portal vein and its branches, and the vesical veins, and can be seen only after death in post-mortem examinations. Nothing definite is known of the diseases to which this parasite gives rise, except the hæmaturia above described. The mucous membrane of the intestines is said to be affected, occasioning dysenteric symptoms, and I have been told lately by a medical man from Egypt that in such cases he has sometimes brought down with the fingers from the rectum nodules

which were attached to the mucous membrane and which swarmed with ova. He has assured me also that the spine of these ova was lateral while that of the urinary ova was terminal. If this should be so, it would account for the statement of Bilharz and Griesinger as to some of the ova having lateral and others terminal spines, which has appeared strange to those who have, like myself, studied only the hæmaturic form. All seem to be agreed that the source of the parasite is infected and unfiltered water; and Sonsino adduces in support of this opinion the fact that Europeans and well-to-do natives never use the water of the Nile unfiltered, and are therefore exempt from the disease, while the lower classes use the water as it comes from the river and suffer accordingly. But I am not aware that anyone has seen the animalcule in infected waters. As a prophylactic measure it is suggested by Harley and Sonsino that drinking water should be conveyed in covered channels to prevent contamination by the excreta of persons infected with the parasite, that it should always be filtered, and that vegetables and fruits should be washed with filtered water before use. How the entozoon penetrates the bloodvessels and finds its natural habitat there is still a mystery. The size of the adult worm and of its ova and embryos precludes the idea that they can be carried through the capillaries or even through the smallest arteries and veins. In one of my cases I once opened a vein in the arm, but found no traces of the parasite in the blood. If the ovum or embryo be the starting-point, it is difficult to understand how they can enter through any part of the absorbent system into the bloodvessels. Dr. Harley supposes that during bathing the leech-like animal may lay its eggs through the skin into some superficial vein, or more likely find its way into the bladder through the urethra.

The case recorded above is the only one in which I succeeded in obtaining apparently a perfect cure. The drug used was oil of turpentine, given in teaspoonful doses three times a day, and continued for about three weeks. I had employed in my previous cases every method which I had read of, or which suggested itself to my mind, but without the slightest effect on the disease as such. When strong tonic medicines were given the general strength may have been slightly benefited; but the examination of the urine revealed in every case the persistence of the parasite. Among other things I tried ten-minim doses of oil of turpentine, with the same quantity of extract of male fern, and carbolic acid, by the mouth and hypodermically, for some weeks, until the system was thoroughly saturated with it, and the urine became smoky. Injections with one-scruple doses of iodide of potassium into the bladder, as recommended by Dr. Harley, I never employed as far as I could wish, and the result was abortive. But in the case he mentioned it does not appear that the success was all that could be desired, for "the patient still passed a few eggs . . . and the ova were in a more lively condition."

P.S.—I should have preferred to delay this communication until I might have had another case for testing again the efficiency of the oil of turpentine; but in the present circumstances, when the disease is attracting so much attention, I thought it my duty to publish the only case of cure by medicinal treatment, so far as I know, and to leave to others, who are now seeing the disease, the opportunity of repeating the use of this drug, and finding out whether we have in it a real specific for endemic hæmaturia.

Beirut, Syria.

**VOLUNTEER AMBULANCE INSPECTION.**—The annual inspection of the Ambulance Company of the Tower Hamlets Rifle Brigade took place on the 29th ult., at the Headquarters, Hoxton. The class numbers thirty members, two or more men being taken from each company of the regiment for instruction in ambulance duties and stretcher drill. The Company was commanded by Surgeon Platt, assisted by Acting Surgeon A. O. White. The inspecting officer, Surgeon-General McKinnon, A.M.D., who was accompanied by Surgeon-Major Don, A.M.D., having witnessed the exercises of drill and stretcher duty, with the application of tourniquets, splints, and bandages, expressed himself as highly satisfied with the inspection. The result, he said, reflected great credit upon Surgeon Platt and the non-commissioned officers and men of the class; and he should have great pleasure in signing the War Office certificates of those members of the class who did not already possess them.

## THE CLINICAL CLASSIFICATION OF BACKWARD DISPLACEMENTS OF THE UTERUS.<sup>1</sup>

By G. ERNEST HERMAN, M.B. & M.R.C.P. LOND.,  
ASSISTANT OBSTETRIC PHYSICIAN TO THE LONDON HOSPITAL,  
PHYSICIAN TO THE ROYAL MATERNITY CHARITY, ETC.

It is a truism in medicine that for treatment to be successful diagnosis must be accurate. The backward displacements of the uterus, retroversion and retroflexion, are met with sometimes without symptoms, sometimes with symptoms; and in the latter case the symptoms, in different instances, differ widely in kind as well as severity. In some cases the symptoms are removed with striking rapidity and completeness by mechanical treatment, while in others the same treatment entirely fails to relieve. Clearly, therefore, all cases of backward displacement of the uterus are not alike; and before we can treat them with any approach to certainty of result, we must be able to make a diagnosis between those cases which require a particular treatment and those which do not; in other words, they must be classified.

The classification at present most in favour depends upon the shape of the uterus: whether it is bent or not; the sharpness of the bending; the greater or less difficulty of straightening it or keeping it straight. Such a classification of course implies that bending is the important feature of the cases to be classified. I believe that bending of the uterus *per se* is, as a rule, an unimportant condition. I have set forth the reasons which induce me to take that view, so far as dysmenorrhœa is concerned, in papers communicated to the Obstetrical Society of London; and therefore I need not here again defend it. I will only make these assertions: that there are many cases in which symptoms associated with retroflexion will entirely disappear, without any appreciable alteration in the shape of the uterus having taken place; and that there are many others in which mechanical treatment, perfectly successful so far as removing the flexion is concerned, fails to remove the patient's symptoms. Cases such as these are not exceptional, but quite common. Of course there are others in which the reverse is the case. But the existence of the former class of cases is enough to show that a classification based merely on the shape of the uterus is not an adequate one, not one which helps in the treatment of backward displacements of the uterus.

To make clear the principles upon which I think that distinctions should be drawn between different cases of backward displacement, I would ask attention to the circumstances in which such displacements occur, and the conditions upon which, in my opinion, the symptoms connected with them depend.

The essential abnormal condition which produces these displacements is yielding of the pelvic floor—that is to say, the muscles, fasciæ, fat, and cellular tissue, which form, as Dr. D. B. Hart has pointed out, a compact layer closing the abdominal cavity below. I see no reason for attributing them to an isolated alteration in any single structure; for it has been shown by experiment<sup>2</sup> that different component parts of the pelvic floor may be separately divided without producing descent or displacement of the uterus. When slight yielding of the pelvic floor takes place, one of the first results is that the mobility of the uterus is increased, and that this organ slightly sinks. The greater mobility of the uterus which the loosening of its supports obviously involves allows it to fall either forwards or backwards. If it were rigid, a falling forwards or backwards of its body would be accompanied with a relative elevation of its cervix in the contrary direction, seeing that the uterus is most firmly fixed at about the level of the os internum. Often this is what takes place, and then we have anteversion or retroversion, as the case may be. But sometimes, instead of altering its position in the manner described, the uterus bends, the body thus sinking without much change in the position of the cervix. Retroversion and retroflexion are

<sup>1</sup> Read before the Hunterian Society.

<sup>2</sup> Savage: *Surgery of the Female Pelvic Organs*, 1870, Pl. xi. Hohl (quoted by Aran): *Maladies de l'Utérus*, p. 980.

s results of a slight degree of prolapse. They are often, eed, valuable indications of a slight yielding of the pelvic r. There are cases in which the uterus, while the patient n the ordinary obetetric position, is not measurably lower the pelvis than natural, and yet we find symptoms. Did look to the amount of descent of the uterus appreciable the medical man as the indication for mechanical treat- nt, we should detect no necessity for it; but the version flexion of the uterus reveals to us the altered condition of uterine supports.

This, then, is the first point to which I would ask atten- n: that retroversion and retroflexion, when pathological, e alike results of slight yielding of the pelvic floor. outhout such yielding they cause no symptoms. Their eence with symptoms is an indication of a degree of pro- pse which may be too slight to be detected in the linary obstetric position, except by the alteration in the elination and shape of the uterus.

The next thing to be borne in mind is that the most mmon cause of yielding of the pelvic floor is par- ition and its effects. After delivery the pelvic floor ould return practically to its condition before the preg- ncy. But this is not always the case. From the injuries the parts which attend childbearing, and from disturbances the process of involution, some loss of tone in the pelvic or frequently results. Hence we find prolapse, retro- rsion, and retroflexion, chiefly in women who have had ildren, and comparatively seldom in virgins. But par- ition also brings with it an increased liability to many lvic disorders: metritis, perimetritis, ovaritis, &c. These nditions are thus very commonly associated with back- ard displacement of the womb, simply because they are one to occur in the same class of patients.

Anteversio and retroversion resemble one another in ing alike results of slight prolapse. But the consequences these displacements differ, for the reason that behind the uterus there is occasionally an anatomical disposition of arts to which there is nothing analogous in front of it. ere are two folds of peritoneum, containing some muscular d fibrous tissue, running back from the neck of the uterus the sacrum—the utero-sacral ligaments. These bands ry very much. Commonly they are small, wide apart, and ose; they may even not exist at all as visible folds of ritoneum. Sometimes they are so strong, tense, and ose together that Douglas's pouch is a sac with a distinct d narrow neck. When this disposition of parts is present d the uterus becomes displaced backwards, its body may, y the intra-abdominal pressure acting on its anterior urface, be forced down into Douglas's pouch, against the margins f which the veins running in the broad ligaments, and re- turning the blood from the body of the uterus, will then be ressed. The return of blood from the uterus may thus be obstructed, and congestion of that organ be the consequence. The body of the uterus may even, there is reason to believe, e so far pushed down as to become grasped by the utero- sacral ligaments, and incarcerated in Douglas's pouch. It s rare to find these ligaments so tense and so close together s to be capable of grasping the body of the uterus. But it s not uncommon to find one or both of them quite strong ough to be capable of exerting pressure on the veins of the broad ligaments when the body of the uterus is pressed low between them.

The utero-sacral ligaments have another effect beside this. When strong and tense they tend to restrict movement of the neck of the uterus in a forward direction. Hence when, this condition of parts being present, the body of the uterus becomes displaced backwards, the utero-sacral ligaments prevent the cervix from moving upwards and forwards. The womb therefore bends, and retroflexion is the result, instead of retroversion, which would be the kind of displacement produced if the cervix were free to move.

I would now ask permission to briefly repeat the im- portant points in what I have been saying:—

1. Backward displacement of the uterus, when pathologi- cal, is a result and indication of slight yielding of the pelvic floor.
2. It is prone to occur in the class of patients who are most liable to inflammatory and other diseases of the pelvic organs.
3. The disposition of parts behind the uterus is sometimes such that when the uterus falls backward, the veins which return the blood from it are pressed on, the return of blood is impeded, and the uterus becomes congested,

On this view of their pathology I would classify backward displacements as follows:—

1. Those which cause no symptoms of any kind.
2. Those in which the displacement (including under that term the totality of the conditions which produce it) is the only morbid condition present, and there is no congestion, the symptoms being those of prolapse only.
3. Those in which there is not only descent, but congestion of the uterus.
4. Those in which the displacement is complicated by other conditions, which may or may not be aggravated by it.

Upon each of these classes I would now offer some further remarks:—

1. It is difficult to get at a correct estimate, at least in this country, of the frequency with which retroversion and retroflexion occur without any symptoms; and it is not of great practical importance. Circumstances every now and then make it our duty to examine the pelvic organs, although the patient has never complained of any functional disturbance referable to them. No one can have made many such examinations without occasionally finding the uterus displaced backward; and from the few such patients whom one is required to examine, one may infer as to the many whom one does not examine that such displace- ments occur also in them. Further, retroversions and retro- flexions have been found post mortem in patients who were known not to have any uterine symptoms during life. But the most important piece of evidence, from the large numbers of which it consists, is that furnished by Vedeler.<sup>3</sup> This physician, who practises in Christiania, examined 414 healthy virgins, and found the uterus retroverted in 45 of them, or 11 per cent., and retroflexed in 13, or 3 per cent. He also examined 506 healthy nulliparæ, and found retroversion present in 47, or 9 per cent., and retroflexion in 17, or 3 per cent. (I have myself examined 111 nulliparæ who sought advice not for uterine symptoms, but for local contagious disorders, and I found retroversion twice present and retro- flexion once.) Vedeler also examined 584 healthy women, each of whom had had one or more children. Among these he found 57 retroversions, or 10 per cent., and 69 retro- flexions, or 12 per cent. In all, out of 1504 healthy women, Vedeler found the uterus displaced backwards in 243, or 16·49 per cent. Out of 1158 women who were suffering from uterine symptoms, he found similar displacements present in 259, or 22·37 per cent. Other writers have published statistics showing the frequency of retroversion and retro- flexion in patients not selected by their seeking treatment for uterine disease, as well as in fetuses and children; but none have investigated such large numbers, or differentiated so carefully between the different classes of patients, as Vedeler. As evidence of his accuracy, I may compare one of his statistical statements with a similar one compiled from his own experience, by Dr. Graily Hewitt.<sup>4</sup> This latter author, out of 1205 women suffering from uterine symptoms and examined by him, found retroflexion in 112, or 9·3 per cent, Vedeler, out of 1106 patients suffering from uterine disease, virgins being excluded, found retroflexion in 112, or 10·1 per cent. As retroflexion is not common in virgins, it is possible that if the few virgins probably included in Dr. Hewitt's tabular statement were subtracted from it, as they have been from Vedeler's, the result might be to make the percentage of retroflexions almost the same.

It is necessary, in classifying the backward displacements of the uterus, to recognise the frequent occurrence of these cases—viz., those without symptoms; because in practice it is essential that we should always bear in mind that as retroversion or retroflexion may exist in a healthy woman without causing symptoms, so either of these displacements may be present along with functional derangement, which it has no share whatever in producing or modifying.

(To be concluded.)

DR. HENRY BROWN, of Northallerton, Yorkshire, one of the honorary surgeons of the Northallerton Cottage Hospital, has tendered his resignation to the committee as medical attendant to that institution.

THE proceeds this year of the Hospital Saturday and Sunday collections in Manchester amount to £7537, being an aggregate increase of £1585 over the sum raised in 1881.

## NEW SAFETY HYPODERMIC INJECTOR.

By J. WARD COUSINS, M.D. LOND., F.R.C.S.,  
SURGEON TO THE ROYAL PORTSMOUTH HOSPITAL.

DURING the last few years treatment by hypodermic injection has been very generally adopted in many forms of disease, and the number of remedies introduced into the system by this method has also steadily increased. Up to the present time the hypodermic syringe has been the only instrument employed by medical men, and the great demand has resulted in the production of many new forms and many ingenious modifications. It is, however, a very general opinion that the syringe does not even now readily and conveniently fulfil all the purposes for which it is required in practice. It is easily deranged, very liable to accidental injury, and always requires very careful manipulation. In any form it must be considered a costly instrument, and certainly very troublesome to clean. When not in daily use it soon gets out of order, and the piston is a constant source of trouble. The washer shrinks or becomes worn and loose, so that the syringe does not work well, and often the operator discovers to his great vexation that the fluid, instead of entering the patient, gradually makes its appearance at the other end of the barrel. I am sure there are few medical men constantly employing hypodermic remedies who have not been disappointed by the faulty action and sudden failure of this delicate little instrument. The vast majority of practitioners, moreover, employ the same syringe for every emergency, and in the case of those who are fortunate enough to possess two such instruments it will be very frequently found that one of them at least is broken or otherwise out of order. The same hypodermic syringe is used for every patient as well as for every remedy, and in fact for every purpose for which it is required both in medical and surgical practice. Sometimes morphia has to be hypodermically injected for the relief of pain, then ergotine has to be administered in the same way during labour, and after that some other remedy must be introduced into another patient. At one time the syringe is charged with perchloride of iron for the treatment of nævus, and at another time it is used for injecting iodine into an indurated thyroid or other glandular enlargement. By the general use of a single instrument much extra labour and additional responsibility are always incurred. The same syringe when continually employed for a large number of potent medicines demands at the hands of the busy practitioner of the healing art the most scrupulous care in washing and cleaning after every operation. Of course this difficulty is readily overcome by obtaining a set of instruments, and by using a special syringe for every patient and for every remedy; but this alternative involves considerable outlay, and certainly renders the administration of hypodermic remedies an expensive form of treatment, and quite beyond the reach of a large class of patients. The syringe always requires care in its application: the eye must generally assist the hand, and the quantity of fluid injected must be regulated by the movement of the piston over an index. The piston is often furnished with a movable stop, and this is no doubt a valuable safeguard. Still it must be remembered that every addition involves extra attention, and that the stop itself has to be properly adjusted before every operation. The hypodermic injection of an active medicine and the due regulation of the dose always involve considerable responsibility, and for this reason it is never my practice to place the administration of any remedy by the syringe in the hands of attendants or friends.

The little instrument which is accurately represented in the figure is intended as a substitute for the hypodermic syringe, and I venture to hope that many of my professional brethren will find it a simple and economical contrivance, and well adapted for every medical and surgical purpose in which such an instrument is essential. The injector consists of two parts: an elastic measuring ball and an injecting needle; the latter is provided with a boss, which serves for a handle during its introduction. It is conveniently furnished with a joint, so that the same needle may be adjusted on several measuring balls. The prefix "safety" is employed to indicate the important fact that its simple construction affords a valuable safeguard against accident, and that it renders an overdose practically impossible. The measuring

balls are made in different sizes, and each ball is capable of holding only a definite amount of fluid, the quantity varying from one to twenty minims. The number placed on the exterior of each ball expresses its capacity, so that by selecting an injector the exact dose can be at once administered.

The instrument can be instantly charged by compressing the elastic ball and inserting the point of the needle or the open end of the joint into the fluid to be injected, and it is generally advisable to repeat this little operation two or three times to ensure the complete expulsion of air. It can be discharged slowly or rapidly under the skin, and this is of course regulated by the pressure of the thumb and finger. It can be washed out and cleaned in a moment, and it is no trouble to keep in order for any emergency. It cannot be broken by an accidental fall, which is too often the fate of the hypodermic syringe, and when it is worn out, it may be

very easily replaced. The injector can be used if necessary under the bedclothes, and as a mistake in the dose is impossible, the performance of the operation does not require the guidance of the eye. It has still another important quality, which cannot fail to increase its utility—the cost is so moderate that a separate instrument can be used for every remedy as well as for every patient.

In conclusion, the safety hypodermic injector will serve many important surgical purposes, and it is a perfect substitute for the syringe in the treatment by injection of nævi and other tumours. It is made for me by Messrs. Mayer and Meltzer, 71, Great Portland-street, and can be obtained from that firm in the form of a single instrument, or in a little case containing several injectors of various sizes. The surgical needle is furnished with three openings at the point to facilitate the escape of fluid into the tissues.

Portsmouth.

## FATAL CASE OF LARYNGISMUS STRIDULUS.

By JOHN McMUNN, L.R.C.P. ED., L.R.C.S.I.,  
LATE DEMONSTRATOR OF ANATOMY, CARMICHAEL COLLEGE, DUBLIN.

ON May 5th, 1882, a woman sought advice for her little daughter, aged one year and nine months. The general health of the patient was good, but at certain times she lost her breath and had to struggle hard to regain it. There were three previous children, all of whom had died in infancy. The duration of disease in the present instance was three weeks; such was the mother's story. The child looked healthy, voice and respiration were normal; the lower gum was swollen and tense over the sites of the temporary molars. Finding here a probable exciting cause of what I believed to be laryngismus stridulus, I determined to lance the gums. As the knife grated on the subjacent tooth the child commenced to cry violently, but at the expiration of one long loud cry it became silent. Breathing was suspended. After the lapse of a couple of seconds a struggle for breath ensued, the face assumed a frightened look, the mouth was widely opened, the trunk and limbs were stiffened, the toes and fingers worked, while the inspiratory muscles were thrown into violent contraction, and signs of asphyxia rapidly developed; the face grew livid, drops of sweat stood on the forehead, the pulse grew feeble and small, while with widely dilated pupils the inturnd and suffused eyeballs seemed to

art from their orbits. Violent inspiratory efforts culminated in general convulsions. Soon all was still, the pulse vanished from the wrist, impulse and sound ceased over the heart, and general muscular reaction took the place of contraction.

**Treatment.**—The child was shaken, its face mopped with wet handkerchief, its back and stomach slapped with the flat hand, attempts to excite vomiting were made, the tongue was drawn forwards, and the vapour of chloroform blown down the throat from the palm of the hand, when muscular relaxation took place; artificial respiration was carried out for some time, while endeavours were made to excite anew the heart's action. Tracheotomy was proposed early, but no reasonings would induce the mother to give her consent.

**Remarks.**—The tongue of a child is fitted to the arch of the palate; it breathes through its nose; in crying the tongue is flattened, depressed, and drawn backwards. Laryngeal obstruction took place after a violent expiration, or at the commencement of an inspiration. Sudden falling of the epiglottis would be thus easily induced, this would induce spasm in the irritable muscles which guard the entrance of the windpipe, while further inspiratory efforts would tend to perpetuate obstruction, especially in the yielding larynx of a child.

Nulla autem est alia pro certo noscendi via, nisi quamplurimas et morborum et dissectionum historias, tum aliorum tum proprias collectas habere, et inter se comparare.—MORAGNI *De Sed. et Caus. Morb.*, lib. iv. Procrimium.

### ST. BARTHOLOMEW'S HOSPITAL.

#### THREE CASES OF ACUTE RHEUMATISM COMPLICATED WITH PERICARDITIS AND PLEURO-PNEUMONIA; REMARKS.

(Under the care of Dr. SOUTHEY.)

THE following notes and remarks illustrate the supervention of some grave complications in acute rheumatism:—

**CASE 1.**—Letitia T—, aged sixteen, a machinist, single, an anæmic strumous-looking girl, was admitted on Oct. 5th with rheumatism and pericarditis, having been laid up at home with articular rheumatism since September 28th (eight days). This was the first attack of rheumatism she had had, and with the exception of scarlet fever and whooping cough she had never been laid up before.

**Condition on admission.**—Perspiring profusely; temperature 102° 6'. Decubitus dorsal; no pain in chest, no cough; she lay very still quite low in bed; mind clear. Tongue white and furred; breath foul; bowels costive. Micturition natural, urine high coloured, otherwise normal. Catamenia just ceased, always regular. Heart apex beat in the fifth interspace below the nipple. Thrill felt with systole, and friction rub heard all over the cardiac region. Pulse 144, soft. Lungs presented no abnormal sounds or dullness. Respiratory sounds clear; respiration 90. Abdomen natural. Large joints, as shoulders, hips, and knees, were more affected than the small ones.

Treatment by twenty grains of salicylate of soda, and seven drops of tincture of opium every four hours. The temperature fell the following morning to 98° 6', and only rose to 100° 2° on that and the next day. Her pains promptly subsided. There was no anxiety; no restlessness. On the thirteenth day of the rheumatism the temperature fell to normal and remained so for three days, but the friction rub became less distinct, and the præcordial dullness increased. She was very drowsy, but woke up to take her nourishment. The opiate was now diminished, and the salicylate given less frequently. There was effusion enough to produce marked præcordial dullness on the twelfth day of illness, and contemporaneously, or nearly so, bronchial breathing and bronchophony were noticed at the root of the right lung, and over more than two-thirds of the left lung. The dorsal position was maintained. Temperature 102° 6'; pulse 120. Symptoms of more active implication of the left pleura

were noticed on the nineteenth and twentieth days of the illness. Pain stitchlike and friction rub. At the same date the dislocation of the heart's apex upwards and outwards, and its disappearance from the chest-wall, too, were well marked. The heart's impulse being felt on the level of the mammae, she was advised to make some effort herself to lie on both sides alternately, and was directed to be propped by pillows into such position. Slight ægophony was noticed over the area of bronchial breathing.

**Treatment.**—Twenty grains of salicylate of soda, and five drops of tincture of opium, every four hours, were repeated. Her temperature fell gradually from the nineteenth day of illness, and her pulse improved. She has been able to sit up in bed and do needlework. Since the twenty-fourth day her pulse has been from 74 to 84; respiration 24; and temperature below normal. Heart-sounds have been clear, and no friction sound has been heard over front of chest. She has had no fever and no cough, but there is still a friction sound synchronous with respiration behind over left lung, some dullness and evidence of feeble air entry at base of lower third of left lung. She entered upon convalescence on the twenty-fourth day of her illness.

The facts in evidence of the course of this patient's disease are:—Pericarditis; pericardial effusion; imperfect air entry into lower lobe of left lung. Bronchial breathing; no rusty expectoration, followed by lateral and posterior friction rub and slight ægophony; rheumatic pleuro-pneumonia, with slight pleuritic effusion. Her temperature fell from 102° 6' to 99° 4' on the ninth day of her illness, pericarditis notwithstanding, and it was not till ten days later that it rose at all high again, 100° 6' and 101°, when she had some fever from her left pleuro-pneumonia. This febrile disturbance lasted four days, and she has since convalesced with one slight relapse.

**CASE 2.**—Eliza P—, aged forty-six, and fairly nourished, prematurely grey-haired woman, single, entered on her menopause at the age of forty-one. She had small-pox at nine years old, and her first attack of rheumatism at nineteen, which laid her up for some weeks; second attack at the age of forty-five, during which she was laid up six weeks. The present illness began three weeks before her admission by swelling and pain in her left foot, which shifted to her shoulders, calves, knees, and lastly wrists. She was feverish, had no appetite, and the pain made her feel sick.

**Condition on admission.**—Sept. 9th: Lying flat on her back, unable to help herself; all the joints of her arms stiff and painful; both wrists swollen; the right red and very tender. Knees and right hip-joint very painful; ankles swollen, red, and hot to feel. Pulse 108; respiration 18; temperature 100° to 101°. Bowels open four times freely; tongue coated with usual thick white fur, and inclined to dry; urine high-coloured; skin moist; pupils large.

**Physical examination.**—Fauces and abdomen yielded negative signs; heart impulse feeble, apex-beat indistinguishable, systolic apex murmur; præcordial dullness increased over both lungs before and behind; rhonchus and catarrhal sounds, but resonance unimpaired. She was placed on the usual slop dietary, and treatment by salicylate of soda was pushed to salicylism, an event established in twenty-four hours.

**Course and progress.**—Three days later her pains were gone; but she complained much of her head, and her cough was troublesome. She took her nourishment fairly, but slept very little. Pulse 78, small and weak; respiration 20. Good resonance over lungs, front and back, and fewer moist sounds. Joints still swollen, and painful upon least movement. General condition extreme weakness; lies always in the same posture. After she had been under treatment twelve days, and therefore on about the thirty-third of her illness, we noticed that her pulse had risen to 96, respiration to 36, and temperature, which had gradually fallen to below normal, rose to 100° 5'. Her cough was more troublesome, and she had a relapse of pains. Pericardial friction was now audible all over the cardiac region in front, and the dullness increasing. The following day the effusion was obviously increased and her temperature went up to 104°, but no physical signs as yet of pressure upon the lungs were observed. The relapse of pains lasted for the usual three days; improved on the fourth, when she slept well without any opiate. But we observed marked dullness on percussion on this the thirty-seventh day of her illness at the base of the left lung. Pericardial friction and præcordial dullness still well marked in front. Since her pericarditis had been ascertained beyond

doubt she had taken repeated moderate doses of morphia, and was propped up in bed. The following day fine pneumonic crepitation could be heard over the dull area of her left lung, with bronchial breathing, transmitted also to the right lung. The colour of the sputum was distinctly rusty. Meantime, notwithstanding the pneumonic complication, the temperature fell to nearly normal. Three days later both legs were anasarcaous, and pitted widely. Stimulants had been given, but were now increased. Two days later improvement commenced, and gradually the dullness receded, and more air entered the affected lung; but her cough, she said, "tore her to pieces." Pulse 96; respiration 42. Her improvement steadily went on; the cough subsided, and she was free from all pain on the forty-eighth day, on which she was able to wash herself.

On the fiftieth day the pericardial friction gradually disappeared, but a pleural rub remained at the left base, and in the left lower lateral region for some days longer. She got up for a short time a few days ago, the sixty-sixth day of her disease.

In this case again there was pleuro-pneumonia of the middle or lower portion of the left lung occurring shortly after the evidence of a considerable pericardial effusion has been established. Yet it ran a favourable—nay, more, a speedy—course to entire resolution, so that in a fortnight or three weeks afterwards the woman was convalescent.

CASE 3.—Emma W., aged nine, a poorly nourished strumous child, with dark hair and pasty anæmic look, was admitted into Faith ward on October 3rd, suffering with acute articular rheumatism and pains in her chest. Her illness had lasted a week, and the pains and swelling had begun in her right hand.

*Condition on admission.*—Temperature 102° 6'; skin hot and moist; cervical glands enlarged. Tongue moist, but furred; abdomen nil; bowels confined; urine scanty. Chief seat of pain and rheumatic inflammation in left hip-joint. Pulse 112; respiration 33.

*Physical examination.*—Heart's apex in fifth interspace outside the left nipple, systolic murmur at apex; pericardial friction at base; præcordial dullness scarcely increased abnormally. Lungs: no morbid sounds, but enfeebled vesicular sounds, and slight dullness at both bases behind, and, laterally, over the right. She was treated with salicylate, and for four days went on remarkably well; her temperature fell to below normal, and pericarditis and endocarditis notwithstanding, she had four days' intermission of her fever; but then her temperature gradually rose, in forty-eight hours, from 97° to 100° 6'; pulse 108. The pain in her heart region was greatly increased, and the præcordial dullness increased also, showing no inconsiderable pericardial effusion, extending all across the chest in front, and well up into the left axilla. She had to be propped up in bed to get her breath, and we recognised dullness, with bronchial breathing, all over the middle portion of the left lung; posteriorly in scapular, interscapular, and subscapular region, also across the root of the right lung. The cardiac region was painted with iodine and poulticed, and some morphia was given in small doses,  $\frac{1}{4}$ th of a grain every four hours. For four days she was extremely ill, then suddenly began to improve. Her temperature fell to 99°; her skin acted, and her pulse was 108; tongue moist and clearing. Dullness on percussion; bronchial breathing, and bronchophony still marked the area of the left lung consolidation; but there was no redux crepitation, and no expectoration, and very little cough.

Again the mode of recovery was in the order which I have exactly observed—namely, that as the præcordial dullness diminished and the effusion was reabsorbed, so the lung consolidation lessened, and air re-entered it, with here and there a little bronchial crepitation; on the twenty-eighth day of her illness, having had no further elevation of temperature or increase of rheumatic pains, sleeping and eating well, the pericardial friction rub became re-established all over the chest in front. Breathing sounds were faintly heard over the area of previous lung consolidation, and she steadily convalesced. Yesterday, however, and for the last week, we have been able to recognise a distinct pleuritic friction sound over the left lung base.

*Remarks by Dr. SOUTHEY.*—I have taken three cases of pericarditis that had well-marked pericardial effusion; no rare, no exceptional cases, but all illustrating a rule so invariable in my experience that I have often wondered it should have escaped comment—the association of pericardial effusion with pneumonia of the lower lobe of the left

lung, or with pneumonia of the middle symmetrical portions of both lungs. In slight pericardial effusion this complication is not met with; in large effusion it is invariable. The left lung is that which is always first and most involved. Is it an effect of pressure? Is it a consequence of dorsal decubitus? Is it a result of the filling up of the posterior mediastinum and that complementary space into which the lung ought to be expanded in the inspiratory augmentation of the thoracic chamber? I believe the latter explanation is the correct one, because the order of physical signs is so very regular. Increased præcordial dullness in front, absence of respiratory sound first between the lower angle of the left scapula and the spine, then dullness on percussion over the same area. The affair terminates in some cases with nothing more than inexpansion of the lung; there is superadded no bronchial breathing, while in others bronchial breathing is well marked. And in some of these, again, the morbid process advances no further; effusion into air cells and solidification of lung tissue are all; a little friction rub follows, but no rusty expectoration, no attendant bronchitis, no fine or redux crepitation; while a third degree of the same lung disease may occur, as in E. P.'s case, attended by both rusty expectoration and fine crepitation and redux crepitation, in other cases where the pericardial effusion is of longer duration or slower absorption. I do not remember to have ever found this pneumonic rheumatic complication independently of pericardial effusion, although I have seen repeated examples of slight superficial rheumatic pericarditis which were not thus complicated. This rheumatic pneumonia has a far more favourable prognosis than either its extent or occasional doubleness would at first thought entitle it to. If my theory of its causation be correct, the treatment I adopted in the three cases I have brought before you, and which experience has taught me is good, is also rational—viz., subduing the joint pains by opium, so that the patient may be moved into a less dorsal position; propping up of the patient by pillows; and administration of stimulants. Rheumatic pericarditis and rheumatic pneumonia, or pleuro-pneumonia are doubtless attended seldom nowadays by a fatal issue, but when bleeding and mercury were principally relied upon for conducting these local inflammations to resolution, and even in the time when alkalies were chiefly trusted to in the treatment of rheumatism, death was far from being uncommon. That the lesser mortality of rheumatism of late years may be due to some alteration in type of the disease I am not prepared to dispute. It may be so, but how can we prove it, and to what are we to refer such an alteration? To better living, better clothing, less wet weather, better draining of our lands, and the more hygienic housing of our population? This may be the case, but I see no evidence of it. But as a hospital physician I avow that we admit no fewer cases of acute rheumatism than formerly; nor comparing the cases I see to-day with those I saw twenty years ago can I perceive any difference in the severity of the general symptoms, or in the degree or kind of its ordinary complication. Still I certainly fail to witness so many autopsies upon cases of rheumatism, and have fewer butter-pat pericardial effusions and solidified lungs, with lymph-coated surfaces, to show my clinical clerks. The cases complicated by pericarditis are less noisy, less restless, less wild in their delirium, often scarcely delirious at all throughout their course. To what shall we attribute this? Is it to salicin, to the salicylates, or to a generally more rational treatment of the disease? I believe it is that we are biased by less theory in our conduct of each individual case, that we do not aim at neutralising some possible lactic acid, destroying some ferment, or even ousting some poison. We neither purge, nor sweat, nor diuretic, nor nourish our patients so much, nor use an exclusive milk, or alcohol, or broth dietary. We seek, at least I can speak for myself, to ease pain by local sedative applications, and rest overstrained nerves by opiates. We wait till stomach catarrh subsides, and then give peptonised or part-digested meats. For three or four days together, we have learnt, patients can live very well on toast-and-water, and if their tongues are very thickly furred will seldom take much else than warm tea or clear meat soups. A little weak brandy-and-water is often a much more suitable nutriment than a pint of milk, although this is thought and believed to be the simplest, the most entire, and the most suitable of aliments. *Pace* my total abstainer; alcohol is physic. In the treatment of acute rheumatism this gastric catarrh is no unimportant affair; and I believe that the real use of salicylate of soda lies in the good effect it appears to exercise upon the

stomach. The tongue cleans rapidly under the repeated doses of the remedy. There is another remedy which seems to be adapted to the later stages of the malady, to the relapsing cases—the cases, too, which perspire very profusely—this is salicin, which some of you have recently seen me prescribe pretty largely. I give ten grains with one grain of the iodide of potassium and ten drops of the tincture of iodide to an adult every four hours. And this remedy doubtless exercises what virtue it possesses upon the gastrointestinal functions, for the appetite and digestion improve under its use.

### SEAMEN'S HOSPITAL, GREENWICH.

TRANSIENT RIGHT HEMIPLEGIA FROM INJURY TO THE HEAD.

(Under the care of Mr. G. R. TURNER.)

FOR the following notes we are indebted to Mr. E. PENNY, house-physician:—

**Maude M.**—aged two years, was brought to the hospital on August 7th, 1882, at 8.30 P.M., with the following history:—At 5 P.M. on the same day she fell off the table, striking the left side of the head with some violence as she fell. She did not complain of feeling any uneasiness until 6 P.M., when she became steadily but rapidly unconscious. Soon afterwards she was seized with convulsive movements of her right arm, right leg, and right side of the face. These occurred every few seconds. When brought to the hospital she had been in this condition an hour and a half.

On admission she was quite unconscious, and could not be roused in any way. Every few seconds she was seized with violent convulsive movements of the right arm, the right leg, and the right side of the face. Both pupils were dilated and insensible to light, but the right was larger than the left. Both eyes were turned to the left side, but the head was quite natural. Her pulse was 60, and very good; respiration 29, deep, but no difficulty about it; temperature 100° F. There had been no vomiting. Her head was examined, and a swelling found over the anterior and inferior part of the left parietal bone, but there was no evidence of any fracture. She was put to bed and an ice bag applied about 10 P.M.; the right arm and leg ceased their convulsive movements, and in the course of a few minutes were completely paralysed, and the side of the face dropped. Her urine was passed in bed from time to time. Her temperature was now 98.4°; pulse and breathing unchanged. About 1 A.M. she was noticed to move both right arm and leg, and from this time the paralysis gradually passed off, the face resuming its normal look last of all, and the leg recovering first. At 8 o'clock in the morning she vomited freely, and almost immediately afterwards she recognised her mother. From this time she rapidly recovered, and left the hospital quite well in four days.

### STROUD GENERAL HOSPITAL.

OVARIOTOMY DURING PREGNANCY; SUBSEQUENT NORMAL PARTURITION.

(Under the care of Mr. STORRY.)

FOR the following notes we are indebted to Mr. R. D. Cameron, resident medical officer:—

**Emily B.**—aged thirty, married, four children, was admitted on April 1st, 1882, with an ovarian tumour, the swelling of which she noticed eighteen months ago. She last menstruated in January, 1882. Being incapacitated from following her household duties, and having lately suffered considerable pain in her abdomen, on the 11th of April (believing her to be pregnant), she was placed under the influence of ether. Mr. Storry, with the assistance of his colleagues, and with the ordinary carbolic spray, opened the abdomen, torsioned one vessel in the abdominal walls, but found no adhesions. He then tapped one large cyst and one small one, tied the pedicle with chromicised catgut, and removed the growth. The uterus was found to be enlarged in the pelvis. The wound was brought together with chromicised catgut sutures. An india-rubber drainage-tube was left hanging from the lower part of the wound, and communicating at the other end with the abdominal cavity, and the usual gauze dressing and india-rubber bandage were applied. Eight hours after the operation two drachms of blood-clot were removed with a syringe from the drainage-tube. The tube itself was removed on the fourth day. The temperature in the axillæ was taken every two hours for the first week and it never rose above 99°.

The patient was catheterised every six hours for the first week. The bowels were opened by an enema on the eighth day after the operation. On the fourteenth day she was sitting in an arm-chair, and a fortnight after this she returned home to her friends.

On Oct. 18th Mr. Storry delivered her of a fine female child.

## Medical Societies.

### MEDICAL SOCIETY OF LONDON.

*Case of Intra-thoracic Aneurism.—Treatment of Pleural Effusion.*

A MEETING of this Society was held on the 20th ult., Mr. F. Mason, President, in the chair.

Dr. HAWARD showed a man suffering from Intra-thoracic Aneurism. The case was that of a carpenter, thirty-eight years of age, who had suffered from what was taken to be left pleurisy in February, 1882, and had been unable to work since. In June last he began to have throbbing in the chest, and came into the hospital six weeks ago. The cardiac sounds were normal at the apex; but in the second left interspace, half an inch outside the sternum, there was a rough blowing bruit blending with the first sound. There was no bulging or thrill, but a faintly visible impulse. "Each expiration is broken by a series of audible puffs, like the distant snorting of a goods engine. These correspond to the cardiac contractions, and are slightly anterior to the radial pulsation. They are increased in loudness by exertion, and are even felt, as well as heard, by the patient; but after prolonged rest in bed they disappear altogether, returning directly he rises." There was a small bronchocele. In reply to questions put by Drs. Habershon, Hall, and Cavafy, Dr. Howard said that the thyroid enlargement had not increased; he was not aware whether the sound was modified by sleep or repose, and thought the disease to be in an early stage; no laryngoscopic examination was made. The case was referred to a committee consisting of Drs. C. T. Williams, de H. Hall, Thorowgood, and Cavafy, and the author.

Dr. FREDERICK HICKS drew attention to an improved form of Apparatus for Paracentesis Thoracis. The advantages were:—1st. That it enabled any degree of pressure, high or low, to be used and maintained during the operation. 2nd. That a manometer, for ascertaining the intra-thoracic pressure either at the commencement or during the operation, could be employed easily and without encumbering the apparatus. Two forms of manometer were shown, and their action explained and demonstrated; in one the fluid was mercury, in the other coloured water. In the latter the disarrangement of the apparatus by the oscillations of pressure during coughing were divided by a mercurial valve, so constructed as to allow a slow current of air at any pressure to pass freely and affect the water-gauge only, whilst any sudden gust of air acted on the column of mercury, and in doing so closed the tube connecting the trocar with the manometer. The construction of this apparatus was explained, and model shown. The use of the manometer was recommended in all cases of paracentesis thoracis. The intra-thoracic pressure was not proportionate to the amount of fluid present. In many cases the fluid was under slight or even no pressure, and in some there was actually suction which might amount to half an inch of mercury. Without a knowledge of this condition it was impossible to estimate the force required to withdraw, which if too low rendered the withdrawal less complete, and increased the liability to the sucking-in of air on the patient coughing or taking a deep inspiration, which, if it were too high, blood was easily expressed, especially so in tapping recent effusions. The same apparatus was also adapted for washing out fluid contained in cavities by alternately injecting from one bottle and drawing into another. This was done through the trocar by means of a three-way stopcock, and the opening or closing of the apparatus was unnecessary during the operation. It was important to prevent the accidental introduction of air into the pleura during the various arrangements and manipulations. An instrument was shown for exploring, and if necessary introducing a drainage-tube into cavities in the lungs resulting from phthisis or bronchiectasis, or introducing a drainage-tube into the pleura in cases of empyema when an anæsthetic is

not given, but only the skin frozen, and rapidity in operation became a matter of importance.

Dr. THOROWGOOD made some remarks on the Treatment of Intra-pleural Effusions. He commenced by pointing out that the operation of tapping the chest for the evacuation of collections of fluid, though old as the days of Hippocrates, had only of late years taken its position as a recognised and successful mode of dealing with such effusions. Before the days of Laennec the difficulty in diagnosis caused the postponement of such operative measures until the chest bulged or an abscess pointed. Then it was thought justifiable to puncture, but it was common for the enfeebled patient to sink from exhaustion before very long. In his own experience rapid evacuation by the aspirator was almost always followed by speedy reaccumulation, and it was hence his practice to wait three weeks generally in a case of obvious intra-thoracic effusion before aspirating. Brief details of cases were given where pretty copious effusion had become absorbed satisfactorily under small doses of mercury, combined with diuretic mixtures. When aspiration became necessary stress was laid on very gradual evacuation of the fluid under a low suction power. In cases of empyema, as a general rule, the open method of continuous drainage succeeded best, but the details of one case were given where an empyema was treated by two aspirations with a perfectly successful result. The first time pure pus was drawn out, at the second operation, twelve months later, a blood-stained fluid appeared, after which steady and complete recovery followed. As a rule, there should not be so long an interval between the tapping, but if pus appear once in the aspirator, and a week or two later the chest seem to have again filled, no time should be lost in again emptying it, so that the lung may have a chance to expand. A case seen with Mr. Bullock, of Isleworth, proved the expediency of this course. A youth had an empyema on the right side, which was evacuated by aspiration. In eight days' time the pus again collected and was let out by free incision, and a drainage-tube was inserted, the operation being done antiseptically. In two months' time recovery was complete, the lung filled well, and there was no deformity. Washing out the chest was only required when the discharge was offensive, the great point being to secure free drainage. Dr. Thorowgood drew attention to right hydrothorax being sometimes caused by cirrhosis of the liver, and the details of a well-marked case were given.—Dr. GREEN pointed out the different objects with which paracentesis was performed in a case of serous and in one of purulent effusion. In the former it was only needful to remove the intra-thoracic pressure, and for this he preferred Dr. Hicks' method. The cases marked by the greatest amount of effusion were those that were most insidious in onset and least attended by pyrexia. In such cases he did not anticipate much benefit from drugs, but advocated early operation.—Dr. C. T. WILLIAMS thought that in very early stages drugs were of service. So far as his own experience went, the cases treated by aspiration did better than the others. The occurrence of pain in the side was an indication for ceasing to withdraw fluid, the remainder being always absorbed. He mentioned a case in which paracentesis was refused, and where treatment by drugs took a year to accomplish the cure. He had not seen much success from division of ribs or cartilage.—Dr. HALL remarked on the importance of a counter-opening in the lowest part of the chest in empyema, to efficiently drain the cavity.—Dr. SYMES THOMPSON thought in sero-purulent cases it was important to empty the pleural sac completely. In such cases Dr. Hicks' apparatus for the introduction of air was useful.—Dr. HICKS said he strongly advocated the use of the least possible amount of suction in treating pleural effusions, the aspirator being used only as a safeguard in case the tube became blocked. The danger of making an opening very low down was that it might get blocked by the diaphragm.—Dr. THOROWGOOD thought that in serous effusion the use or not of the aspirator was of minor importance.

#### MEDICAL OFFICERS OF HEALTH SOCIETY.

AT a meeting of this Society, held at Adam-street, Adelphi, on November 17th, the President, Dr. J. W. Tripe, in the chair, a paper was read by Mr. ROGERS FIELD, M.I.C.E., on "Certain less recognised, but highly important, points in the Drainage and Ventilation of Houses," of which the following is an abstract:—Three

sanitary principles govern house-drainage. These are: 1. All refuse matter must be completely and rapidly removed from the house. 2. There must never be any passage of air from the drains or waste-pipes into the house. 3. There must be no connexion between the drains and the domestic water-supply. These principles, although so simple, are very frequently neglected. The first goes absolutely to the root of sanitation; for were it strictly complied with there would be no leaky drains, no polluted subsoil, and no production of foul gases in the drains from decomposing organic matter. There cannot be a greater mistake than to assume, as is commonly done in investigating drainage, that if water runs away with freedom this is all that is required; numerous cases are on record where the sewage from houses has apparently run away freely for years, but where the greater portion of it has really been leaking out of the drains into the ground under or close to the house. In illustration of this point the author quoted two cases in his own practice: one in which the connexion with the sewer was actually found to be blocked with shavings, which had been left in when the house was built three years before; the other that of a school, in which the drainage from the lavatories had leaked through disused drains under the floor of a large portion of the building, and where, although there was a mass of filth in some places seven feet deep, no leakage had been suspected. If the drains are exposed and found clean and jointed with cement this is not sufficient; the tops of the joints may be good and the bottoms bad. The only safe method is to actually test the drains by plugging them at the lower end and filling them with water; very few house drains indeed stand this test. Even if the drains are outside the house, it is a mistake to assume that it is unimportant whether they are sound; for not only may sewage leak out of faulty joints and percolate under the house, but foul air may be drawn into the house. It is important to realise how small an amount of deposit will create mischief by decomposing and degenerating foul gases, a mere irregularity of the joints even when the drain has a good fall is sufficient to cause this. There is no better test of the condition of the drains than the amount of smell emitted from a ventilating opening, for if drains be properly laid and in thorough working order, practically no smell should exist. Examples were given. Faulty forms of traps and water-closet apparatus were strongly condemned by the author, and diagrams descriptive of good and bad closets were exhibited. The principle that there should never be any passage of air from the drains or waste-pipes into the house was then considered, and the means of isolating the house drains from the public sewer, the necessity of keeping the drains outside the house, their ventilation as well as that of the soil-pipes, the position of the waterclosets, the disconnexion of the sanitary fittings inside the house from the drains, were referred to. It was insisted that the danger should be guarded against of trusting too much to those parts of the drainage of a house which are visible as an index of the condition of other and important parts which are concealed, and an instance was mentioned of a house the drainage of which had been recently reconstructed, and where all the sanitary arrangements appeared at first sight to be perfect, but where a subsequent examination of the drains, which were under the house, showed that the joints were in many places defective, and at one point the pipes were not jointed at all, but a space left large enough to put a hand in, though it was stated that special care had been taken to make the drains watertight. Old drains, which had no outlet connected with gullies, were found beneath the passages and rooms; the housemaid nearly died of typhoid fever, and beneath the room she occupied was found an old drain with a large amount of foul deposit. A long list of other defects was described, leading to the conclusion that the drainage instead of being very good was really so radically defective throughout that it was necessary to reconstruct the whole of it. Another instance was given in which a lady and her cook were attacked with erysipelas and blood-poisoning shortly after occupying a house. Various alterations were made in the drainage in the absence of the family, but on their return the lady was again attacked with erysipelas, and shortly after other members of the household. Again alterations were made, and again the lady was attacked with erysipelas, and the housemaid with typhoid fever. An examination of the house by the author showed that an old stoneware drain in the scullery into which the sink formerly discharged, before it was disconnected, had not been removed, and

ugh stopped with cement, the stopping was imperfect, thus allowing the air of the drain to enter the house. The author next considered the various ways in which foul air from faulty drainage inside the house passes to different parts, and pointed out the opportunities which are given for the passage of air from one part of a house to another, depending chiefly upon windows and doors; the latter, of course, mainly acting by drawing air through passages, staircases, and doors. But other means must also be borne in mind; and an interesting point was given of the passage of foul air along bell-wire pipes, the proximity of the bell-pull to the fireplace giving increased opportunity for air to be drawn from a distance to this part of a room. Channels for gas-pipes and for hot-water pipes also not uncommonly give facility for the admission of foul air. In connexion with this part of the subject, a remarkable instance was given of a particular bed in a school, the occupants of which were constantly the objects of slight attacks of pneumonia, with tendency to phoid. In this case the foul air was conducted from a lavatory, where there was defective drainage up a staircase, and, impinging on the ceiling of the dormitory, was reflected to the bed where the sickness occurred. An interesting account was given of the cause of the Duchess of Connaught's recent illness. Defective drainage was found in the basement of the house; and after numerous experiments, the means by which the foul air entered the Duchess's bedroom were discovered. These showed that it was only when occupying certain positions in the room that she would be exposed to the influence of the foul air, while in a bed she would escape. As a matter of fact, in twenty-four hours after sitting on a sofa in one of these exposed positions Her Royal Highness's symptoms fully developed themselves. These two cases were illustrated by diagrams. The necessity of a thorough disconnection between the drains and the domestic water-supply was then dwelt upon, and the mistakes most commonly made in this particular pointed out.—In the discussion which followed the President, Dr. Buchanan, Dr. de Chaumont, Dr. Corfield, Mr. E. C. Robins, Dr. Bate, Mr. Jacob, Dr. Rogers, Dr. Poore, and Mr. Shirley Murphy took part.

#### CAMBRIDGE MEDICAL SOCIETY.

AT the meeting on November 3rd (Professor Humphry in the chair) the subject for discussion was "Sudden Death (irrespective of Hæmorrhage) during Confinement, or within three weeks after—the Causes, &c."

In answer to a circular requesting members to inform the President whether they had seen any cases, and if so to give the particulars, thirty-five replies were received. A total of twenty-nine cases were supplied by fifteen persons; twenty-one members had not seen a case. Professor HUMPHRY had made an analysis, and divided the cases into three classes—viz., of sudden death (1) before the birth of the child; (2) soon after delivery; (3) within three weeks after confinement. Under the first heading five cases were reported, in two of which death was apparently due to exhaustion from long and complicated labour. Fifteen cases were reported under the second heading: in two the cause of death was not apparent; in three the labour was tedious and severe; two were cases of inverted uterus; one case was marked by diabetic coma and one by albuminuria; three were cases of placenta prævia; in one case rupture of the uterus occurred; and in one parturition supervened during an attack of typhus. Under the third heading eleven cases were returned: nine of the deaths were attributed to embolism; in one case there was albuminuria, and in another apoplexy.

Dr. STOWERS (of London) exhibited a male patient, aged twenty-eight years, who had been under his care eight months suffering from Acne varioliformis. The disease first appeared on the skin in front of each ear, and had throughout been almost entirely limited to the face, scalp, and upper part of chest. Deep punched-out scars, or pocks, marked the sites of the pustules, so that the deformity remaining was equal and similar to that of confluent small-pox. Several unsuccessful attempts at inoculation were made to test the character of the pus. The patient recovered entirely under the influence of increasing doses of arsenic, aided by the topical application, by puncture, of carbolic oil, thus supporting the belief previously held by Dr. Stowers that the affection was in no way related to syphilis.

## Reviews and Notices of Books.

*Quain's Elements of Anatomy.* Edited by Dr. ALLEN THOMSON and Professors SCHAEFER and THANE. Ninth Edition. London: Longmans, Green, and Co. 1882.

THE name of Quain has long disappeared from the list of editors of this work, and now that of Sharpey is also missing. The late Professor Sharpey had been so long and honourably associated with the production of its successive editions; his writing and supervision conferring on the chapters on the general anatomy of the tissues and the anatomy of the viscera their especial charm of style, their marvellous accuracy, and progressive development in accordance with whatever has been new and at the same time true in modern research, that it is hard to realise the issue of an edition without his name on the title-page. But, alas! he has passed from amongst us, and we are reminded by a simple preface of the great debt which anatomical and physiological science in England owes to his writings and example: "This ninth edition of 'Quain's Elements of Anatomy' is dedicated to the memory of William Sharpey, M.D., LL.D., F.R.S., formerly Professor of Anatomy and Physiology in University College, London, and during thirty-five years one of the editors of the work." The chief responsibility of the revision has therefore devolved on Dr. Allen Thomson, who now for the third time appears as editor, in association with Professor Schäfer, who was responsible for most of the histological portion of the preceding edition, and Professor Thane, to whom has now been allotted that part of the subject which deals more especially with descriptive anatomy. We congratulate Professor Thane on his succession to so honourable a distinction, and we consider the choice an admirable one, having regard both to Professor Thane's extensive and accurate anatomical knowledge, and to the fact that to his predecessors in the Chair of Anatomy at University College the work itself owes its origin, its special features, and many of its most marked improvements.

The first volume of the new edition contains the descriptive anatomy of the bones, joints, muscles, vessels and nerves, and a special chapter on superficial and topographical anatomy, whilst the second volume is devoted to general histology, the anatomy of the viscera, and embryology. The chief alteration in the text of the descriptive anatomy is in the chapter on the bones of the head, to which a short but very clear account of the methods of modern craniometry, with examples of the varieties of the skull in some typical races, has been added. As minor changes we find the position of the liver in the living subject described according to His, the classification of the cranial nerves according to Soemmering, and the divisions of the mediastinum mainly in accordance with the views of Struthers. The superior division of the mediastinum is introduced, and its boundaries and contents are for the first time laid down in a text-book. We much prefer the divisions of the pleural interspace which were suggested by Professor Wood in his article on "The Arch of the Aorta," in the *Journal of Anatomy and Physiology* for 1863, to those of either Professor Struthers or the editor, and it is in that article that the great importance of a more accurate division is first referred to, and the "superior mediastinum" as a distinct region named and defined. The laborious and careful investigations of Wood on the true position of the aorta and the thoracic contents, which have only been introduced into the last two editions of "Quain's Anatomy," demand far more notice than the general description given by Struthers. Even the very term "superior mediastinum" is used by Wood. The sections on the bones, joints, muscles, and nerves show marks of careful revision, and those on the vessels are now much improved by coloured drawings. We could wish that some of the illustrations of

the bones, especially those of the skull, and even of the more important nerves, had been replaced by new and larger woodcuts, for when the details are so very numerous, any representation which is overcrowded with reference-numbers is of but little value to the student. The descriptions of the bones and joints, although admirably done from a purely scientific standpoint, must be greatly enlarged and modified before they will come into general use by medical students. Whether topographical anatomy as a separate subject is not a little out of place in this work is a question on which opinions will be divided, but all anatomists will agree that Professor Thane and Mr. Godlee have given us a most accurate and thorough epitome of the relations of the various structures to the surface, which cannot fail to be of great value to the physician and surgeon.

In the second volume more considerable changes have been made than in the first, for in the past six years great advances have taken place in histological and embryological research, and the most important and trustworthy observations have been incorporated in the text. These alterations have been made very judiciously, and have been supplemented by many original investigations by the authors themselves. In the histology of the cell and of the tissues we find the latest views of the editor, Klein, and Flemming, illustrated by many new and beautiful drawings from specimens made by Professor Schäfer himself, whilst the researches of Key and Retzius, Ranvier, Recklinghausen, Ehrlich and other less known microscopists have every attention. Many new drawings from Henle, Schwalbe, and Luschka have been added in illustration of the anatomy of the central nervous system, and so much new matter has been introduced into this part of the work that it almost seems to be a new treatise. The most important alterations in the chapter on Embryology are due to the researches of His, and particularly to those of the late Professor F. M. Balfour, whose important contributions to this branch of science have considerably modified many of the older teachings on the subject. The value of the monograph on the Development of Elasmobranch Fishes, and of his masterful treatise on Comparative Embryology, can only be correctly estimated when we see the observations and views contained therein at once accepted and acknowledged by the father of embryology in Britain, Dr. Allen Thomson.

The careful and thorough revision, the many improvements, and last, but not least, the bibliography at the end of every section in the second volume, not only again mark out "Quain's Anatomy" as the best work on the subject in the English language, but make it in many respects superior even to such classic works as those of Henle, Cruveilhier, and Sappey. It is now a text-book of which every English anatomist must feel proud.

It is but justice to the publishers to add that they have not failed in performing their share of the task of producing the work. The type is unusually clear and bold, and by extra care in printing many of the old engravings have been almost transformed.

*The Student's Guide to Materia Medica and Therapeutics in Accordance with the British Pharmacopœia.* By JOHN C. THOROWGOOD, M.D., F.R.C.P., &c. Second Edition. London: J. and A. Churchill. 1882.

*A Medical Formulary Based on the United States and British Pharmacopœias, together with numerous French, German, and Unofficial Preparations.* By LAWRENCE JOHNSON, A.M., M.D. London: Sampson Low, Marston, Searle, and Rivington. 1882.

*Catalogue of the Collections in the Museum of the Pharmaceutical Society of Great Britain.* 1878. Compiled by E. M. HOLMES, F.L.S., Curator of the Museum.

WHATEVER satirists may say to the contrary, the value of medicines in the practice of physic is only beginning to be realised. The growing efficiency of chemistry as a hand-

maid of medicine, analysing medicinal substances and separating in minute forms their active principles, and the closer study of the action of medicines, both from a physiological and pathological point of view, have resulted in therapeutical discoveries of the greatest interest and value. To take one instance only, that of the action of pilocarpine, the active principle of jaborandi. What action of any of the older diaphoretics will compare in certainty and efficiency with that of pilocarpine, which will produce salivation and diaphoresis within ten or fifteen minutes of its administration? Of course the discovery of such powerful agents involves a corresponding obligation in those who use them to do so intelligently and carefully. Hence the increasing importance of works on *materia medica*, three of which we have named at the head of these remarks, and which, in their several ways, will be found very useful on the table or in the carriage of the practitioner.

Dr. Thorowgood's book has worthily reached a second edition. It assumes a knowledge of, or the means of reference to, the British Pharmacopœia. But it explains the principles of the chief pharmaceutical processes employed in making the preparations of the British Pharmacopœia. It would be greatly enhanced by a more complete supplementary notice of drugs which, though not in the British Pharmacopœia, are used by the best practitioners in this or other countries. Unfortunately, the British Pharmacopœia does not at any given time include some of the most valuable preparations and drugs. Notwithstanding this defect, Dr. Thorowgood's book is a most excellent one, not only for students, as he modestly says in the preface, but for practitioners. It gives a clear and concise account of the chemical and pharmaceutical bearings of a drug. But the therapeutical part of the book is also admirably executed. It indicates the personal opinion and experience of the author, in a way not fanciful and far-fetched, but judicial and practical.

The work of Dr. Lawrence Johnson, of New York, has a plan larger than, and different from, Dr. Thorowgood's. It aims at giving the drugs and preparations in common use, and includes those of all the Continental, British, and the United States Pharmacopœias. It seeks too to give not merely pharmacopœial preparations, but formularies from leading hospitals and practitioners. It is weak in the statement of therapeutical doctrine and experience, but is nevertheless a work of very great convenience, and one implying much labour and trouble on the part of the author.

The Catalogue of the Collections in the Pharmaceutical Society of Great Britain is a collection which every practitioner would do well to take an opportunity of seeing whenever it presents itself. It is useless for a practitioner to attempt to keep pace with the rapid achievements of organic chemistry and advanced pharmacy. Every week discovers a new alkaloid or a new preparation. But there is no place where an inquiring practitioner can spend a more profitable half hour than in the museum of the Pharmaceutical Society, where he is not unlikely to have at once his pleasure and his knowledge enhanced by meeting Mr. Holmes, the author of the very valuable catalogue under notice, which we may hope soon to see superseded by a new edition.

*Diseases of Women.* By ARTHUR W. EDIS, M.D. Second Edition. London: Smith, Elder, and Co. 1882.

WE so fully reviewed the first edition of this work that we shall content ourselves with a few remarks on the second edition. Of the errors which we pointed out many have been corrected, but some retained. For instance, our author adheres as tenaciously to the pathological view of "glairy cervical mucous like white of egg" as this clings to the place of its birth. This is an accurate description of the normal and healthy secretion of the cervix, which may,

indeed, be associated with other pathological conditions, but shows that, whatever else is wrong, the secreting apparatus of the cervix is right. The retention of such an error as this must result in the unnecessary and prolonged treatment of numbers of healthy women, and it is in our opinion as easy and as rational to cure this condition as it would be to put a stop to the secretion of gastric juice by the stomach or saliva from the mouth. We are not sure how far the actual words of the description are answerable. "Glairy" is a mysterious and ill-sounding word, and "glairy tenacious discharge" sounds terrible indeed. What woman could live comfortably with a "glairy tenacious discharge" from her uterus? Although Dr. Edis has become decidedly less heroic in his second edition, we think that the mention of any operation endangering life should include a careful definition of the objects in view, the risks run, the prospects of success, and the indications calling for, or at least justifying, the procedure. Such an operation as division of the cervix should surely not be left as a "something to be done." In treating the subject of Sterility, Dr. Edis recommends (p. 478) the preliminary elimination of male incompetence. Is the examination necessary for ascertaining this, then, to become a practice with "the student and junior practitioner"—to whom the work is addressed—whatever may be Dr. Edis's custom in such cases? It remains to say that the second edition has in no way changed the opinion we formed of the first.

*Ogilvie's Imperial Dictionary of the English Language.*  
Edited by CHARLES ANNANDALE, M.A. London and  
Edinburgh: Blackie and Son.

THE amount of information contained in the older editions of this work has rendered it invaluable to English-speaking peoples for the last quarter of a century, and we cordially welcome this, the latest edition, and predict for it a large and well-deserved sale. Enriched as it is by the addition of new quotations illustrative of the various changes a word may undergo, and the shades of meaning it may possess, it may be regarded not solely as a mere dictionary, as that word is commonly understood, but as a valuable addition to the English encyclopædic literature of 1882. We note with special pleasure the correct and clear meanings that are given to scientific words—medical, chemical, zoological, &c.; and can well understand the pains and trouble that have been taken in these various departments; the woodcuts are numerous and admirably executed; the classical quotations and derivations with which the work abounds are extremely appropriate to a dictionary of a language which is indebted for words to so many different sources as is the English language. Printed in clear legible type, on good paper, and bound in a solid and useful form, this book fully merits the name "imperial,"—a word which is defined in it, amongst other meanings, as "anything of unusual excellence." It is one of the few works of its kind that we are able to speak of in terms of high commendation, and we feel that Mr. Chas. Annandale and his coadjutors deserve praise for their labours, which, it is stated, have extended over ten years.

*Christmas Cards.*—The development which the "institution" of Christmas cards has obtained is, it must be confessed, almost marvellous. It is impossible to estimate the amount of time, ingenuity, and artistic skill expended in the production of the "things of beauty" which at this season of the year find their way into nearly every English home. Two packets of elegant trifles of this class have reached us. One comes from the ARTISTIC STATIONERY COMPANY, LIMITED, Dyers' buildings, Holborn, and includes a selection of choice designs on card and gelatine, and etchings on satin. The cards are remarkable for chasteness and originality, and are deserving of high praise. The

etchings especially are worthy of commendation. The second packet is from the firm of Mr. WILLIAM LUKS, of Bedford-street, Covent-garden. These cards are of five sizes, and consist for the most part of floral groupings, standing out in life-like form and colouring on substantial and worthily permanent mounts. They are certainly beautiful specimens of art.

## New Inventions.

### CARBOLIC SPRAY PRODUCERS.

ON two previous occasions (Oct. 25th, 1879, and July 24th, 1880) we have written in terms of praise of the spray producers manufactured by Messrs. Matthews Brothers, of Carey-street. We have now to record some further improvements adding to the efficiency, safety, and convenience of these apparatus. The improvements may be enumerated as follows:—1. Filter of finely perforated metal tube to top mount, protecting delivery-point and valve from the impaction of foreign particles from the interior of the boiler. 2. Filter to protect delivery-point. 3. Joint near "point" giving universal movement, and forming stopcock when at right angles. 4. Copper reservoir for carbolic solution, at the base of the stand, doing away with the ordinary glass jar, and enhancing the portability, as well as keeping the lamp cooler. 5. Metal filter, instead of sponge, on india-rubber tube from the carbolic acid solution. 6. Simplification of slide-tube regulating lamp flame. 7. Increased size of feed-hole to boiler, expediting filling, and allowing of thorough examination of interior of boiler. 8. Horned "point" protector, instead of the hood. 9. Change in safety-valve, which is now provided with set screw to facilitate cleaning. The piston of the valve, instead of being solid, is now composed of three fine rods, thus enabling steam to escape through the whole of the steam-way, and relieving pressure in half the usual time.

### EUCALYPTOL SPRAY.

THIS apparatus, manufactured by Messrs. Mayer and Meltzer, was devised by Mr. Robson, of Leeds, with the view of producing an aseptic and antiseptic atmosphere. It consists of a series of wide metal tubes, through which the air is forced by bellows. The first tube is filled with cotton-wool, which acts as an efficient filter, and the second and third tubes are filled with pumice-stone saturated with eucalyptol. The air is distributed by means of five coralline nozzles working on a universal joint. It has been used by Mr. Robson himself, Mr. Teale and Dr. Churton, at Leeds, and by some metropolitan surgeons. If the air thus filtered and saturated with eucalyptol be as efficient as the carbolic spray, it is needless to say that Mr. Robson's apparatus possesses very obvious and important advantages over the older spray-producers.

### "THE DISCOVERY OF TRICHINA SPIRALIS."

To the Editor of THE LANCET.

SIR,—If I had sent to press my note to Mr. Wormald acknowledging the parts enabling me to make the discovery of the microscopic worm, an earlier date would have been attached thereto. But I was more concerned in the working out the evidences of its structure and zoological position than in a mere announcement of the contents of Mr. Hilton's cysticerci. The consequent delay giving me the opportunity of referring to Mr. Paget's observation on the same subject, will not, I feel assured, be interpreted as a mere zoological elucidation of a species of entozoon for a knowledge of which I had been indebted to another, and of which I had not been a *bona fide* and independent discoverer.

I am, Sir, yours obediently,

Sheen Lodge, Richmond-park, Nov. 30th, 1882. RICHARD OWEN,

# THE LANCET.

LONDON: SATURDAY, DECEMBER 9, 1882.

IT is well understood that the Scottish Universities are opposed to the establishment of Conjoint Boards by the compulsory fusion of the existing examining bodies in each division of the kingdom. They are satisfied with things as they are; and well they may be. They educate probably as many students as all the London schools put together, and their Degrees, though only qualifications in medicine, entitle the holders to registration. Still, it is not so easy to see why they should think it consistent with their dignity and duty as great and famous medical schools to oppose legislation which, in the opinion of the great bulk of the profession, of the Medical Council, and of successive Governments, is necessary in the public interest, and which would be a great boon to the poor medical student, on whose back such heavy burdens of education and examination are laid. It is true that their graduates, under the system of licence by a Conjoint Board, would not be able to register without first passing the final examination of one of the Conjoint Boards in clinical subjects. But let us see how the Commissioners put their proposal with regard to the Scotch as to all the other universities of the kingdom.

"We do not propose in any way to interfere with their teaching [that of the Scotch universities], nor do we believe that students will cease to recognise the cheapness and excellence of their education. We propose that all their examinations, save the final one, should, if satisfactory to the Medical Council, be accepted by the Divisional Board, and we require from them no concession which is not required from every other university and corporation in the kingdom, &c. &c."

In other words all the university examinations are to be accepted but the closing one in clinical subjects, at a cost, probably, of a five pound note. Persons who are not possessed with the fear of the imminent ruin of the Scotch universities will be apt to think that legislation in this line will actually benefit the Scottish universities. A student will be apt to say to himself, "By passing the university examinations, I not only secure a degree and an honourable title, but ensure exemption from all other examinations by mere licensing authorities, but one that will give me no trouble and cost me little money. I will make an extra effort to enter the profession through a Scottish university, where so much is done for medicine." This seems so clearly the tendency of such a system that we should expect to see the Scotch universities eagerly accept it, apart from their binding duty to consider the question from the standpoint of what is best to give public satisfaction. It may be said that this privilege of the universities—Scotch and English too—is to be dependent on the satisfaction of the Medical Council. So it should be. The Scottish universities ought to be sufficiently conscious of the worth of their examinations and their education to invite the criticism of the Medical Council. They are no friends of the universities or of Scotch graduates who shrink from this.

Professor TURNER, in his dissent from the proposal of the Royal Commissioners to form Divisional Boards, speaks with proper pity for the student in regard to any legislation calculated to increase the cost of examinations. But we do not see that under a proper Conjoint Scheme the University graduate at least will be mulcted of so much as he is at present by the existing authorities. A graduate is seldom content with his mere degree; he wishes to have a diploma besides, and generally takes it from a College of Surgeons. Under the proposals of the Commissioners he will, after passing his University examinations and the clinical examination of the Conjoint Board, be completely qualified, and have an honourable Degree for a much less sum than he now must generally pay for similar advantages and multiplied examinations.

It will be the more unseemly if the Scottish Universities oppose any well-considered legislation on the lines of the Royal Commissioners, inasmuch as the interests of these Universities are safe-guarded by the Commissioners on a proposal offered by Professor TURNER himself, and endorsed by Professor STRUTHERS, before the Select Committee of the House of Commons. Here is a quotation from the evidence of Professor TURNER before that Committee:—

"Question 3155, by the chairman, Mr. W. E. Forster. Is there not another direction in which the difficulty might be met?—There is: and I have another suggestion to make, and that is, that the conjoint examination, so far as regards university candidates, should be restricted to the clinical examinations—that is, the examinations in clinical medicine, clinical surgery and midwifery, which would test whether a man really has a knowledge of practice, because that, I submit, if there is to be any legislation, is really all that is needed. I would consider that all that is required, if you are going to have legislation, is that you should satisfy yourselves that every man going into practice has got that amount of information which is necessary for practice, and that may be got through an examination in clinical medicine, in clinical surgery, and midwifery. That is an alternative proposition; but I consider that our clinical examinations, as at present constituted, are an ample test of competency to practise."

Professor STRUTHERS put in a paper before the Committee which, though ten years old, he said "exactly expressed the present opinion of the Faculty of the University of Aberdeen." It said:—

"The security which the Faculty desires would be given by the introduction of the following provision as a substitute for Clause 10, Section 2: 'Candidates for admission to the examination, who are also candidates for university graduation, and have passed the examination or examinations conducted by the university on the accessory and fundamental sciences of medicine, including chemistry, natural history, botany, anatomy, and physiology, shall, on their having completed the curriculum of study required for examination by the medical examining board, be entitled to be admitted to the final examination of the board on payment of a fee not exceeding five pounds.'"

Dr. GAIRDNER objects, in a letter to Dr. GLOVER, published elsewhere, to being supposed a party to such offers as are involved in the above answers of Professor TURNER and Professor STRUTHERS. And it is quite true that he much preferred the alternative proposition to allow assessors representing the Medical Council to take part in the University examinations. But Dr. GAIRDNER will not deny that

Dr. GLOVER was substantially right in saying that the Commissioners have adopted a proposal made by eminent representatives of the medical interests of Scotch universities with whom he was in general accord. Since this proposal was made, the principle of a reduction in the number of Licensing Boards has received the support of a Royal Commission, and the Scottish universities will be very badly advised if they resist legislation on a Report embodying safeguards for them suggested by Professor TURNER and Professor STRUTHERS.

THE term "dyscrasic albuminuria" has been applied to the albuminuria which depends on a change in the blood, and is supposed to be independent of structural alterations in the kidney. Its mechanism has often been the subject of speculation, and attempts have been made from time to time to elucidate the problem by experimental research. It is true that the exact conditions of dyscrasic albuminuria in man cannot be exactly reproduced in animals, but the injection of various albuminoid substances into the blood of animals has thrown considerable light on the probable origin of this form of albuminuria. Such bodies as egg-albumen and casein, injected into the veins of an animal, pass into the urine, at least in part. The explanation which is usually given of this fact is that these albuminoid bodies have a diffusive capacity which is higher than that of the albuminoid bodies contained in the normal serum, and hence the latter remain in the blood, while the former pass out through the kidneys. The fact appears to be true within certain limits. ESTELLE and FAVERET, pupils of LÉPINE, and working under his direction, observed that by injecting into the veins one of the albuminoid constituents of normal serum, serin or globulin, there is produced in the animal serinuria or globulinuria respectively—i.e., a special albuminuria in which the substance injected reappears in the urine. LÉPINE, in a note published in the *Lyon Médicale*, thinks that these results cannot be readily explained on the hypothesis that the effect is due to a difference in diffusibility. It seems, *a priori*, unlikely, he thinks, that the manipulations necessary for the isolation of serin or globulin should so change their diffusive power as to account for the result. At any rate, the hypothesis is unable to explain the albuminuria which results from the injection of normal serum into the veins. It was formerly believed that the latter effect could be explained by an assumed increase in arterial tension, but we now know that this tension is not sensibly modified by the injection into the veins of a small quantity of serum. The phenomenon can, LÉPINE believes, be explained by considering the particular conditions in which it occurs. It does not happen if a small quantity of perfectly fresh serum is injected into an animal of the same species; it occurs, however, if serum of the dog is injected into a rabbit. This is in harmony with the fact that the transfusion of small quantities of perfectly defibrinated blood into an animal of the same species produces no ill effect, but if dog's blood is transfused into a rabbit, there is necessarily dissolution of a certain number of red globules, with consequent hæmoglobinuria. LÉPINE suggests that the same explanation may be given of the albuminuria which results from the injection of heterogeneous serum. The effect is due to the injurious action, of the substance injected, on the blood-corpuscles in one case, on the kidney in the other. All our

tissues are susceptible to a dyscrasic influence, however trifling, and the renal glomeruli do not escape the general law. The albuminuria may be the result of the influence on the tissues of the glomeruli, and its only manifestation. As far as our methods of observation go, the serum of the dog seems to be identical with the serum of the rabbit, but however slight is the difference between the two, it is sufficient to determine an albuminuria, and may be sufficient to irritate the kidney of the subject transfused. It is not, therefore, surprising that isolated globulin or serin injected into the veins should produce a similar irritation of the kidney.

A grave difficulty in the way of this hypothesis is the fact that the result of the irritation is the passage of the irritant substance only, and not of the normal serum-albumen of the blood. LÉPINE admits this, and suggests an explanation which, at first sight, appears very hypothetical. He suggests that the pores of the renal filter are only enlarged on the contact of the irritant molecules, and close immediately after the passage of these, just as our soft tissues permit the passage through them of foreign bodies, as needles, although no permanent solution of continuity results from the passage. According to this hypothesis, a dyscrasia, in order to give rise to albuminuria, need not necessarily act upon the albuminoids. It is sufficient that either the albuminoid or the saline materials of the serum should be modified quantitatively or qualitatively. In support of this proposition he cites some experiments which he has made, in which transient albuminuria has been produced in dogs by injecting chloride of sodium in the proportion of one per thousand of the body-weight of the animal. If the solution is but little concentrated, and the injection is slowly made, no perceptible effect is produced except the albuminuria, which results apparently from the action of the altered blood upon the kidney. We may point out, moreover, that the theory of LÉPINE derives support from experiments lately published by KNIPERS on the effect of the injection of egg-albumen into the blood. STOKVIS and LEHMANN had shown that the amount of albumen which then passes off by the kidney may be actually greater than that which is injected into the blood. KNIPERS only corroborated this statement in two out of twenty-two cases. In several instances hæmoglobinuria was also produced, and apparently depended on the quantity of water which was injected with the albumen. It occurred whenever the amount of albumen exceeded two per thousand of the body-weight of the animal, and irrespective of the addition of chloride of sodium. Moreover, the effect was not confined to the excretion of albumen. An estimation of the nitrogen and phosphoric acid, made in six experiments, showed a constant increase in the elimination of phosphoric acid, and an occasional increase in the elimination of nitrogen. The latter occurred especially in the cases—not rare—in which the animals lost flesh. Intravenous injections were followed by intense and prolonged dyspnoea. The most important fact ascertained by the experiments, so far as the origin of the albuminuria is concerned, is that the kidneys almost invariably presented structural changes. The kidneys were swollen, the epithelium of the tubules presented cloudy swelling here and there, its nuclei were increased in number, and minute fatty globules were scattered through it. The

glomerular capsules were sometimes distended by a mass, solid after the organ had been boiled; sometimes the capsule was simply raised, and appeared separated from the glomerulus by an empty space. The interstitial spaces of the kidney appeared to be enlarged, and their cell-elements increased in number. Hyaline or granular casts were found in the tubules or in the urine. The occurrence of these structural changes certainly gives some support to the theory of LÉPINE (not altogether new), that it is by an action on the kidney that blood-states cause albuminuria.

THE Edinburgh Royal Maternity<sup>1</sup> is a small hospital in which about two hundred women are annually delivered. Its medical staff consists of several of the leading accoucheurs of the Scotch metropolis. They serve the hospital in turn, each for three months, and they publish accordingly quarterly reports of the work of the hospital. There is an out-door department, with which we are not at present concerned. The quarterly reports laid before the Obstetrical Society of Edinburgh, and published in its Transactions, are of considerable value in the respect that they make known from time to time the amount of success which has been obtained in the working of the charity. The example thus set by the Edinburgh hospital is deserving of imitation by the lying-in hospitals of London as well as by those of the provinces. There are four lying-in hospitals in London, in which from twelve to fourteen hundred women are confined every year, and no account of the working of any one of them is made known to the profession, unless the annual report issued to the subscribers be regarded as such. A full report of the medical work carried on in them is nowhere published, and the loss to science thus accruing is, or ought to be, incalculable. The method of carrying on the work of the Edinburgh charity has within the last few years been greatly altered. The mortality had always been high, and, with a view to reducing it, the systematic use of antiseptics was introduced, and Dr. HALLIDAY CROOM drew up a series of rules to be observed by the nurses and by the students attending the practice of the hospital. These rules have regard to the disinfection of the hands of the students and attendants, of instruments and appliances, and of the generative passage. Most of these rules are unexceptionable, but some of them are calculated to encourage an unjustifiable sense of security. Such are the rules relating to sponges and linen fabrics, which absorb infective material with great readiness, and retain it with great obstinacy, so that it is not possible to be certain that they have been rendered again non-infective and harmless by washing, boiling, or soaking in a solution of carbolic acid. They can, however, be entirely dispensed with: diapers can be replaced by cotton-wool or fine tow, and sponges by cotton-wool, all of which can be burnt when used. In this way a very grave source of danger may be completely removed. The rule prohibiting the admission of visitors unless provided with a special pass from the resident medical officer appears unnecessarily severe, especially when it is borne in mind that women when taken in labour are admitted from the poorest and most wretched homes. Disease may doubtless be carried into hospitals

by visitors, and this is more especially true of children's hospitals. In hospitals where the inmates are adults such occurrences are rare, and it has yet to be proved that the poison of the acute specific diseases (if we except erysipelas) plays any part in the production of puerperal fever. The introduction of these rules into the practice of the hospital appears to have exercised a beneficial influence. From the foundation of the Edinburgh Lying-in Charity up to November, 1880, the maternal death-rate was nearly 2 per cent. In May, 1879, a new hospital was opened. The building was completely new, "with all the most modern sanitary improvements, examined by the most competent sanitary authorities," and yet, under these apparently favourable circumstances, between May 1879 and Nov. 1880, out of 320 women delivered in the institution, 12 died, and 10 of these from metritis—a mortality of nearly 3·8 per cent. During the three quarters ending April 30th, 1881, 159 women were delivered, and 5 died; while during the year ending April 30th, 1882, 225 women were confined, and 3 died. This is a high death-rate, but there are doubtless causes contributing to it which are not met with in out-door practice, for during the last year there were in 225 cases, 22 preterm or complex labours, and 17 instrumental deliveries. During the previous nine months, of 159 deliveries, 18 were forceps cases, and 10 were of a complex or preterm character. This high proportion of abnormal and instrumental labours may in some degree account for the high mortality. At the same time a stricter supervision of attendants, and greater care in carrying out antiseptic precautions, will probably reduce the mortality below any yet seen in the hospital.

THE general concern which is excited by the serious illness of Mr. FAWCETT will be shared, in a special manner, by all members of our profession, and has doubtless been increased by the change in the character of the later bulletins. Some surprise has been excited by the altered language regarding the disease which followed the consultation with Sir WILLIAM JENNER on Saturday last, and the rather vague announcement that the fever accompanying the diphtheria had "assumed a typhoid character." It is not difficult, however, to find an explanation of the change. The coincidence of diphtheria and typhoid fever has been several times observed. Indeed, it is a matter of surprise that the two diseases are not more frequently concurrent. Their conditions of origin, as far as we understand them, are nearly the same. Although the causes of each often elude discovery, especially those of diphtheria, there is a strong consensus of fact to show that each occasionally arises from the inhalation of sewer gas. It is a moot point whether, in the cases in which the two are coincident, the patient is actually suffering from two distinct maladies, or whether the diphtheritic membrane in the throat is the result of the poison which causes the typhoid fever. There is much to be said in support of either view. There is one other disease in which throat diphtheria occurs not unfrequently—scarlet fever. The cases of scarlet fever thus accompanied are always severe; and it seems certain that the false membrane in the throat is the result of the scarlet fever poison, and is not the expression of a coincident and independent affection. This fact renders it conceivable that the typhoid fever poison may also be capable of causing a similar local affection.

<sup>1</sup> Quarterly Reports of the Royal Maternity and Simpson Memorial Hospital.

But, on the other hand, diphtheria is an extremely rare complication of typhoid; false membrane is, as a rule, absent, even in the most severe cases, in which the poison is most intense in its action. Hence it is clear that, if the diphtheria is due to the typhoid poison, the latter must have, in such cases, some special character. But the fact that the throat affection runs its course and subsides, while the typhoid fever continues, makes it on the whole more probable that the two diseases are coincident, the results of separate poisons, doubtless generated together, and obtained from the same source. If the diphtheria occurs, as in the case of Mr. FAWCETT, early in the course of typhoid fever, the existence of the latter can scarcely be suspected at first. Even in an uncomplicated case of typhoid fever, the nature of the disease can rarely be diagnosed with certainty until the end of the first week or ten days. Thus diphtheria commencing nearly at the same time as the typhoid would have run its course, and be in process of subsidence, before the nature of the typhoid malady was clear, or even its existence could be suspected, since its only symptoms up to the end of the first week or ten days might also be due to the diphtheria. Indeed, it is somewhat remarkable that the existence of the typhoid fever should have been discovered in the case of Mr. FAWCETT before the subsidence of the throat affection gave significance to the continued pyrexia.

This combination of diseases is one of the most grave with which medical art is called upon to deal, and the anxiety which it has caused is certainly well founded. Happily it is not necessarily fatal. A case in Paris, on which we commented some time ago (*THE LANCET*, June 25th, 1881, p. 1037), presents considerable analogy to Mr. FAWCETT's, and the patient recovered. The false membranes in the throat made their appearance on the fourth day of the disease, and continued until the twelfth. The abdominal symptoms and eruption of typhoid were characteristic, and the patient had to contend against the additional complication of an attack of phlebitis on the nineteenth day. The unquestionable gravity of initial complications of typhoid is perhaps apt to be over-rated. It seems impossible that a patient should live through such a disease as typhoid fever when it supervenes on another malady (for instance, pneumonia), itself sufficiently severe to prostrate him completely, and yet every physician can call to mind such cases in which the typhoid fever was borne at least as well as in other instances of like severity, with no preliminary disease to lessen the patient's strength. While, therefore, there is cause for much anxiety, there is also reasonable ground for hope that a life so valuable may be spared.

WE regret to have to report another case of a practitioner signing a certificate of death for a case seen not by himself but by his assistant. The mother testified that the child was taken ill on Oct. 5th, and taken to a surgery, where it was seen and prescribed for by an assistant. The usual certificate was given by the principal. The defence was that the latter had seen the child in September, which was denied by the mother, and that the assistant was qualified. It was not explained why, if the assistant were qualified, he had not signed the certificate. The magistrate considered that the law had been broken, not corruptly but knowingly, and ordered a fine of £5 and costs.

## Annotations.

"Ne quid nlmis."

### THE LATE PROFESSOR FRIEDREICH OF HEIDELBERG.

THE first article in the current number of Virchow's *Archiv* is contributed by the illustrious editor himself, and is devoted to a memoir of Nicholas Friedreich, one of Virchow's early pupils, who died a few weeks since of aneurism. Professor Virchow remarks that on the occasion of the festival given in his honour last year, all but one of his former assistants during thirty years were living—that one being Professor Hoffman of Basle, who died in the previous year. Since then two others have passed away, Karl Hüter and Nicholas Friedreich. The latter was at Würzburg when Virchow came there in 1849, and had just distinguished himself, with his fellow-student Gegenbaur, by a memoir upon the skull of the axolotl. It was natural that Friedreich should be attracted to Virchow's side, for he seems to have been a man moulded in the same type, full of the spirit of scientific inquiry; and an attachment grew up between them from that time. The former pupil invariably, in after years, submitted his work to the criticism of his master, and became a constant and prolific contributor to the pages of the *Archiv*. In the preface to his best-known work, that on Progressive Muscular Atrophy, Friedreich records the indebtedness he was under to Virchow; and now in the article above referred to the latter shows to how great an extent their feelings were reciprocal. Friedreich's last writing is published in the same number of the journal that contains this tribute to his memory. We do not desire to criticise it, although we cannot endorse its conclusions, striking as the cases apparently are whereby they are supported. Briefly, it consists in the advocacy of a surgical method of treatment of certain cases of inveterate hysteria similar to that which, some sixteen or seventeen years ago, was so indiscriminately urged by a late London gynaecologist, with the most disastrous results to himself. Where, however, the latter employed the knife, Friedreich advises the actual cautery; and, in referring to the history of the subject, he cannot understand why in London the question was treated upon moral rather than scientific grounds, yet in spite of his arguments, and the melancholy circumstance that forces his paper upon attention as being the last product of an active mind, we do not think the practice will be reintroduced into this country, even under the limitations he enjoins.

### THE LAST HOURS OF THE PRIMATE.

SOON after our last report of Archbishop Tait's condition (October 7th) he seemed somewhat to improve; the lungs cleared, the respiration decreased in frequency, falling to 29 per minute; the heart maintained its improved condition, but the pulse seldom fell below 100. To outside observers he seemed to be gaining ground; he sat up for several hours each day, and transacted a good deal of business, but on one occasion, when an attempt was made to place him upright, it was immediately seen that his muscular power was very defective. The respiration at once became very frequent, and the pulse rose to 130, but the aortic murmurs did not again develop. He was well able to take food, which was apparently assimilated, so that hopes were entertained by his friends that he might be able soon to make a change to the South. This was not, however, the opinion of his medical attendant, and in that he was supported by Sir W. Jenner and Sir W. Gull. Occasionally the contents of the stomach were thrown up suddenly, without apparent cause; now and then there was a tremulous motion in the left arm and leg, which occasionally extended to the right; the tremor would last a few minutes, and was similar to that

of paralysis agitans. This tremor culminated in a convulsion which affected the left arm and leg, but not the face; this was manifest when an attack came on whilst Dr. Carpenter was present. These attacks were similar to those experienced by his Grace fourteen years ago; they recurred at first at intervals of a few weeks, then after a few days; they were generally (not always) preceded for a day or two by a continuous nausea, and a condition which he himself described as a bilious state. When the colder weather set in about the middle of November there was a rise of temperature from 99.5° to 101°, a return of congestion in the lungs and dulness on percussion, but the cough was not very troublesome, and the expectoration did not again become rusty. Notwithstanding this rise, the Archbishop disliked to remain in bed, and continued to sit up for a few hours every day until four days before his death. The troubles connected with the state of the kidneys continued, and on several occasions it was manifest that a large cyst existed, which occasionally filled, and gave rise to great discomfort; this was usually remedied by gentle pressure with friction, by which means the cyst was emptied. During the last week of his illness the pulse gradually became more frequent and the respiration shorter; the tremulousness became more manifest on the right side until early on Friday morning, when a more general convulsion occurred, but not affecting speech or consciousness. From that time the temperature began to fall, and the urinary secretion to diminish in quantity. Three or four tremors occurred before the end came; there was one on Saturday night, which he recognised by calling out, "It is coming—it is coming," and after it had passed he asked for a little water, and soon after sank into a doze. The temperature at that time was 96.8°. There were two slighter convulsions in the course of the night, and he passed away without any other changes than falling temperature and slowing pulse and respiration, until the latter ceased at 7.15 A.M. on December 3rd. There was a very peculiar state of the body on the following day. The wrinkles had disappeared from the face, all sign of heaviness and suffering were gone, and the countenance of the Primate was more like that of a young girl smiling in her sleep than that of an aged man; this impression was produced by his wavy curls and whiskerless cheeks.

#### A SCOTTISH NATIONAL CHANGE.

WHEN Dr. Johnson issued his famous sally upon the poor of the Scottish people there was much of truth in the remark that oats—or, at least, oatmeal—constituted the diet of the northern people, while they were reserved for the use of the horse in England. Scotchmen need not feel ashamed of the charge, as upon this food work of a kind to render the world a debtor to their country has been done; and the simple surroundings of many a Scottish youth have been the fitting preparation for a life of honourable toil and subsequent distinction. With such a history as that of the Scottish peasantry—for it is specially to them that our remarks apply—their well-wishers will be anxious that changes should have due consideration, and that they be not undertaken rashly or in ignorance. We fear that the characteristic simplicity in Scottish, and perhaps English, rural life is being fast lessened, that the aggregation of our population, which goes on apace, is productive of physical evils to those specially affected, while those left in the country accommodate their method and manners to those of the town with but doubtful advantage to their own wellbeing. In nothing is the change more manifest than as it affects the food of the people. Attention has recently been given to the fact that food literally makes the man, and a nation well fed must be a nation prosperous and happy in most respects. But the nutritive value of foods differs so much that greater attention might profitably be given to the question, and the people

shown that quantity alone ought not to be considered irrespective of the force-giving powers of food. Judged either physiologically or economically, the Scottish national diet of porridge and milk must be highly esteemed, and it is questionable whether any other food in common use is so useful as a force-giver, while so cheap and easily obtained. During recent years we learn that oatmeal has become less and less the food of the Scottish people. Even in the agricultural districts, where this article forms part of the labourers' wage, it is no longer freely consumed by that class, but sold or exchanged for articles such as tea and other doubtfully nutritious commodities which are now habitually used as substitutes. Milk has long been allowed to farm labourers in sufficient quantity to be of the greatest value as a food for the young, but in many cases this too is stopped, and money given instead. The working classes should know how their best interests are affected by this gradual change, while farmers and other employers must observe the working power of their *employés* gradually diminish as insufficient and improper food takes the place of that till now in general use. There is no more important question than the best and cheapest food for the general population of a country; and a nation which by good fortune has hit upon a system so excellent as the Scotch should not lightly throw aside the advantage thus gained.

#### ORCHITIS IN TYPHOID FEVER.

ORCHITIS is one of the rarest complications of typhoid fever. So uncommon is it that its occurrence is not even mentioned in Murchison's classical account of the disease. Nevertheless a good many cases have been lately recorded. An instance (of doubtful nature) was described by Bouchut in 1867; and Dr. Duffey observed in the same year, at Malta, no less than eighteen examples of this complication of Maltese fever. Since then a number of cases have been observed in France, and at the beginning of last year its occurrence in the Mediterranean fever was described in our columns by Ellis. Another example has been lately published in *L'Union Médicale* by M. Sevestre, who has added some interesting comments on the complication. The patient had suffered from a severe attack of typhoid, of ordinary type, and was in full convalescence, free from fever, walking about the ward, when he suddenly experienced considerable pain about the groin, and it was found that the right side of the scrotum was reddened, and the testicle swollen and painful. The epididymis was not involved, but the spermatic cord was slightly painful. The left testicle was normal. There was no urethral discharge. The inflammation gradually subsided, and had disappeared at the end of six days. The affection usually comes on in the same sudden manner as in this patient. In most other cases the onset occurs during convalescence—three, six, ten, and even twenty days after the cessation of pyrexia. In no recorded case had any complication accompanied or followed the fever to which the orchitis could be referred. The onset of the testicular inflammation is usually attended with a return of fever, and the temperature may even rise to 103° or 104° F., the pulse to 120, and violent rigors may occur. In such a case, especially if the local pain is slight, the physician may think he has to do with a relapse of the typhoid, and in a case of unexplained pyrexia during convalescence from this disease the testicle should always be examined. In very rare cases the orchitis comes on before the primary fever is over. When the pain is slight it may only amount to a sense of uneasiness in the testicle, which is not always exaggerated by pressure. When severe it does not amount to a very intense degree, and is never neuralgic in character. The inflammation is always unilateral, and the epididymis is never involved. It appears to be more frequent on the right side than on the left (in seven out of nine observations). In

majority of cases (eight out of twelve) the affection is acute; the inflammation does not go beyond the congestive stage, and it ends in from six to ten days. Occasionally even a permanent degree is not attained, and transient hyperæmic swelling is noted. Sometimes its course is less benign; the inflammation attains a considerable degree of intensity, abscess may be formed, and the suppuration may go on to complete destruction of the organ. Moreover, in the cases which run a mild course the affection may leave a permanent induration about the epididymis, and in one case atrophy of the testicle ensued. The pathology of this condition is still obscure. That it should recur especially in certain epidemics affords no explanation of its origin. Of the theories proposed, that it is a rheumatic inflammation, allied to the inflammations which follow scarlatina, or that it is due to a thrombosis in the spermatic vein, none is very satisfactory.

DOWNING COLLEGE, CAMBRIDGE.

WE are glad to learn that Downing College, Cambridge, assuming the position in the university which was contemplated in its foundation. It was founded at the beginning of the century for the especial promotion of law and medicine. A professorship of each of these sciences was richly endowed, and all its Fellows were required to engage to one or other of these professions, and it was presumed that they would promote the study of law and medicine in the university. This is now being done. Besides the professors there are now three lecturers in each science, and the students can thus obtain all the personal superintendence of their studies required for the examinations without incurring the expense of private tuition. The number of students both in law and medicine has been recently increased, and last year the success in University honours in the two sciences was marked. An additional impulse to the study of medicine has recently been given by the election to a fellowship of Mr. Alex. Hall, M.A., M.B., who was highly distinguished in the Natural Sciences Tripos, and is at present Demonstrator of Anatomy in the University Medical School. He acts as adviser to the undergraduates in their medical studies, and also lectures in the college.

THE BOARDING-OUT SYSTEM v. WORKHOUSE SCHOOLS.

A DEPUTATION waiting on the President of the Local Government Board the other day, to urge the expediency of extending the boarding-out system instead of establishing more workhouse schools, was regaled with the more or less ratifying intelligence that the subject is "under consideration." Mr. Dodson went even further than this; he expressed his pleasure at the volunteer service which takes the form of raising institutions for the shelter and support of pauper children. It is well, we know, to cherish a contented mind and to cultivate thankfulness for small mercies. And it is gracious to be grateful for official utterances of the class which would seem to have afforded so much satisfaction to this deputation. Meanwhile, no one should be misled by statements which mean nothing. If the boarding-out system is to supersede that of training and teaching in workhouse schools, the desired result must be gained in the legislature, not at the feet of the President of the Board. It is ridiculous to sue any longer in the audience chamber of Mr. Dodson. The battle must be fought in Parliament, and the sooner the better. Every deputation which leaves Whitehall satisfied is a new obstacle in the way of reform, a fresh excuse for delay. Nothing can possibly be more fatal than to be told that a subject pressed on the attention of the President of the Local Government Board is "under consideration."

COLONIAL MEDICINE.

AT the forthcoming International Colonial and Export Trade Exhibition to be held in Amsterdam from May to October, 1883, a section is to be devoted to the subject of Colonial Medicine. In founding this section, it is the intention of the Executive Committee to limit it to its scientific aspects, with a view to promote knowledge upon sanitary and medical conditions in the colonies. The section is to be divided into three classes. The first class will deal with hygiene, and will comprise such matters as sanitary commissions, water supply, food adulteration, bathing and sanitary establishments, schools and public buildings, burial-grounds and cremation, sewerage, trade diseases, measures adopted against endemic, epidemic, and contagious diseases, also malarial disease, and diseases attributable to malarial sources; parasitical diseases, and their prevention; prostitution, vaccination, epizootic diseases, and mortality statistics. The second class is devoted to the organisation of the medical services, comprising the direction and administration of the civil and military medical services and the regulations governing medical practice, special medical education of colonial doctors in the mother country, medical education in the colonies, &c. The third class deals with the attendance upon and transport of the sick and wounded, and their treatment by the natives; it includes such subjects as hospitals, transport, medical literature, medical treatment and hygienic customs of the natives. Dr. Stokvis is the president of the section, and in September it is intended to hold an International Congress for Colonial Medicine in connexion with the Exhibition. The Government, having received intimation of this scheme, have communicated with the Royal College of Physicians, and that body has deputed Drs. Barclay, Bristowe, Corfield, Stevenson, and Sir Joseph Fayrer to consider upon the manner in which this country shall be represented in the section. As there is no country in the world that has wider colonial possessions than Great Britain, we may expect that a warm interest will be taken in the Exhibition here, and that no effort will be spared to provide material, upon which the success of the undertaking will largely depend.

DISLOCATIONS OF THE HUMERUS.

THERE are various methods proposed for reducing dislocations of the shoulder, some of which have proved efficacious when the old-fashioned heel-in-the-axilla method has not succeeded. Mr. J. E. Kelly, of Jervis-street Hospital, Dublin, some years since read some notes before the members of the Surgical Society of Ireland, upon certain expedients which he had found useful in reducing various dislocations. He has recently published a new method of reducing a dislocation of the humerus, and his connexion with Jervis-street Hospital, where a very large number of accident cases are annually admitted, and his private practice, have afforded him many opportunities of testing its utility. For the operation a bed firmly fixed is of importance, and should be, if a subglenoid dislocation is to be reduced, about three inches lower than the great trochanter of the operator, while one lower still by a couple of inches for the anterior dislocation, and a little higher for the posterior, allows the force to be applied advantageously in the direction of the glenoid cavity. The patient is placed on his back on the bed, close to the edge, with his head low. Mr. Kelly divides the operation into two stages. In the first, the operator places the injured arm at right angles to the body, and standing against it, with his side to the patient and his hip pressed firmly into the axilla, folds the arm and hand of the patient closely round his pelvis, and fixes the hand firmly, by pressing it against the crest of his ilium. The second stage, during which reduction is effected, consists merely of a rotation, or version, of the operator's body with a force and rapidity which vary with

the nature of the dislocation. For any additional manipulation the surgeon has the hand next the patient's axilla disengaged for such manœuvres as lifting the head of the humerus into its cavity, making traction upon it forwards or pressure backwards, according to the nature of the accident. By this method no assistant is needed, and an anæsthetic does not require to be administered.

#### THE MODERN SWORD OF DAMOCLES.

It would be difficult for a malevolent genius to devise any more dangerous apparatus than a long stout wire stretched from house to house across a public thoroughfare. In some unexpected moment, under extraordinary pressure, perhaps a heavy weight of snow, it is not merely possible, but likely, that it will fall to the ground, and in falling must almost inevitably cut in two all it strikes. Nevertheless, this modern sword of Damocles hangs suspended over the head of the Londoner in nearly every street through which he passes from murky morn to drizzly eve. And, strange to say, the threatened Londoner seems in no way disturbed by the jeopardy in which he is placed. If it were otherwise, if the fear of danger dogged his footsteps, he would simply take measures to have the impending peril removed under the Nuisances Act. It is useless to remonstrate, because, doubtless, the representative Londoner has an interest in the multiplication of telegraph and telephone wires stretched overhead, and if an "interest" be vested in any nuisance or source of danger it is safe. Meanwhile, for the sake of the provincial folk and foreigners who visit the metropolis, if not of the mass of the population, it would be well to take these wires down before some terrible calamity occurs. Mr. W. H. Smith told a deputation which waited upon him a few days ago that it was vain to hope that anything would be done in the session of Parliament which has just ended. He was right. We should like to supplement this extra-Parliamentary utterance with the remark, that it is perfectly useless to expect that in any session of a legislative assembly, or by any official board, anything will be done so long as public opinion betrays no consciousness of the danger that exists. A spice of peril adds piquancy to life, and the reflection that we may "at any moment" fall victims to some hideous catastrophe is rather exhilarating to the human mind, than calculated to disturb its habitual tranquillity. This being so, it is perhaps a pity that anyone should harbour a desire that the modern sword of Damocles may be speedily removed.

#### COMPLETION OF THE IRISH CENSUS.

THE Commissioners charged with taking and reporting upon the Irish Census have just issued their General and Final Report, which bears date September 21st last. The Irish Commissioners have succeeded in anticipating the publication of the corresponding reports for the other divisions of the United Kingdom. The first volume of the Scotch Census Report was issued a month or two since, but no portion of the Report upon the English Census is yet available to the public. The comparatively early appearance of the Irish Report has certainly not been attained by reduction of the statistical tables, which in abundance of detail bid fair to considerably exceed that which will be available either for England or Scotland. In noticing some of the county parts of the Irish Census we expressed a doubt as to the real value of the remarkable elaboration of detail with which the information was published. Now that the report is before us in its entirety we are scarcely inclined to change this opinion. The Irish Census Report consists of four huge folio volumes, averaging more than 1000 pages each, dealing with the four provinces; and supplemental to these the General Report now issued contains 427 pages, uniform in size.

When we consider that Ireland contains but a seventh of the population of the United Kingdom, it is almost alarming to contemplate the possibility of reports at equal length for England and Scotland. This would signify that the aggregate report for the United Kingdom should consist of thirty-five folio volumes, with an average of 900 pages in each. It would be interesting to know whether there is any local demand in Ireland for the fully detailed county parts of the Irish Census, as it is this form of publication which in great measure caused the enormous length of the report. We much doubt the real value of such elaboration of detail and calculation for small populations like those of many of the Irish counties. This opinion, however, notwithstanding the very abundance of information given to the public with unprecedented promptitude, only adds to the well-deserved credit which the Irish Commissioners have earned for their successful completion of this remarkable work. Some of the information dealt with in the General Report just issued will serve for comment on a future occasion.

#### ELECTRIC INTERCOMMUNICATION.

THE possible use which electricity may eventually prove to be in making us less dependent upon personal servants, by affording ready means of communicating with and utilising those whose duty it is to serve the public at large, is foreshadowed in the prospectus of the Electric Fire-alarm and Signals Company. The Company proposes to establish stations throughout the metropolis which shall serve as centres for various districts, having, as near as may be, a circular form, the radius of the circle being about a quarter of a mile. In this way each house in the district will be brought into electric communication with a centre not more than a quarter of a mile off, and it is reckoned that every message sent to a centre will be answered by messenger within three minutes from the time of sending the signal. The signals which may be sent will be, as a rule, four in number—viz., "Messenger," "Cab," "Police," and "Fire." The last two signals may be transmitted automatically from empty houses by means of the automatic burglar-detectors and fire-detectors, the former of which are put in action by the slightest opening of a door or shutter, and the latter by means of a spiral spring which lengthens and establishes an electrical communication on being heated above a certain point. The centres will be established close to cab stands, and a staff of messengers and police will be on duty at the centre night and day. This arrangement seems to be, in theory at least, a very desirable thing; and it is stated that, in America, companies having a similar object have done business at a considerable profit. As far as fire is concerned, the system has already been established to some extent in London; and in his report for the year 1881, Captain Shaw, of the Metropolitan Fire Brigade, states that the fire alarm circuits "have undoubtedly enabled us in some instances to save both lives and property."

#### DISEASE AND CHRISTIANITY IN NORTH CHINA.

THE first annual report of Mr. Harold Schofield, M.B., in connexion with the China Inland Mission, excites a hope that we shall be favoured with many others. Mr. Schofield's place of work is at T'ai-Yuen-fu, Shansi, North China. From a medical point of view the report is most interesting. The total number of cases treated in the year was 40 in-patients and 3488 out-patients. The new cases included 284 opium-smokers. The principal diseases, in a numerical respect, are anæmia, dyspepsia, bronchitis, neuralgia, diarrhoea, syphilis, and gonorrhoea; skin diseases, especially eczema, impetigo, scabies, ulcers, and abscesses. Among surgical cases are two dislocations of the femur and

two of the humerus. The skin group of diseases is the most numerous; next in number is the group of opium-smokers, who, by the way, are the only patients who pay for their medicines; next the diseases of the respiratory organs. Mr. Schofield notices, as others have done before, the commonness of hæmoptysis, and the fact that it is often attended with little impairment of the general health or other indication of lung disease. He has not seen one single case of acute rheumatism, which he attributes largely to the exceeding dryness of the air. Indeed, he remarks on the almost complete absence of all acute disease. The climate differs from that of England in the much greater extremes of heat and cold and in the much greater dryness of both air and soil. Anti-vaccinationists should study his remarks on small-pox and its consequences, especially blindness. 'Small-pox,' he says, "is accountable for the destruction of an immense number of eyes, both among children and adults." We congratulate Mr. Schofield on his report and his work, and wish him every success.

#### SMALL-POX IN BAVARIA.

DR. VON KERCHENSTEINER, one of the leading medical officials in Bavaria, has recently published some details as to the ravages of small-pox in that country during the period from 1871 to 1881. In the first-named year the disease had been introduced from France, and 30,742 persons in Bavaria were attacked, this number representing a proportion of '68 per cent. of the population. Of the vaccinated patients 13·6 per cent died, and of the revaccinated only 8·2 per cent.; while of the unvaccinated, no less than 60·2 per cent. were carried off by the complaint. The following figures illustrate the results of several years in succession at a later time within the period under review.

	Percentage of deaths of vaccinated persons.	Percentage of deaths of re- vaccinated persons.	Percentage of deaths of un- vaccinated persons.
1877 . . . . .	10·8	8·2	53·1
1878 . . . . .	11·8	8·1	39·5
1879 . . . . .	13·6	—	41·1
1880 . . . . .	12·8	12·2	37·0
1881 . . . . .	10·3	8·1	48·3

#### CROWDS AT OPEN WINDOWS.

CROWDS at open windows to see processions are fruitful sources of work for the doctors. After hurried gatherings and exhausting waits, which first overheat and then weaken the body, sight-seers take their places at open windows and expose themselves to draughts which they would not on ordinary occasions dare to face. Children, too, are "put out," as it were, to "catch cold." This is what happens whenever there is anything to be seen in the streets, even in November and December. Already the consequences of the procession on Monday last are beginning to make themselves apparent. Why are parents with an average amount of common sense so careless? Why do they not wrap up and clothe their children sufficiently when this peril is to be incurred?

#### THE NEW CHELMSFORD INFIRMARY.

THERE has been a day of great concord and rejoicing in Chelmsford in spite of a great deal of agricultural distress in the neighbourhood, feelingly alluded to in the speech of the chairman of the proceedings. The occasion was the laying of the foundation stone of a new infirmary and dispensary. According to the local newspapers there was only one omission in the proceedings, that of any allusion to the labours in the past of the honorary medical officers. We willingly believe that this was accidental, but it was not the less conspicuous, and will, we hope, not recur in the greater occasion which is still in the future.

#### THE MEDICAL SOCIETY OF LONDON.

THE large room of the Medical Society of London was filled to overflowing on Monday evening, Dec. 4th, when Dr. Heneage Gibbes exhibited a large number of specimens of bacteria from various sources. The chief interest centred in the specimens of tubercle bacillus, which were shown as occurring in both bovine and human tubercle, and in the sputa of phthisical patients, the slides being prepared according to the method already described by Dr. Gibbes in these pages (Aug. 5th, 1882). Besides tubercle bacilli the collection included the so-called "typhoid bacillus," several specimens of bacillus anthracis and of the same under cultivation, bacilli from diphtheria and septicæmia, from sheep-pox, from the Welbeck poisoning case, and as a concomitant of putrefaction. Dr. Gibbes read a short paper on the methods of staining employed, and on the localisation of the bacilli in the various forms of tubercle. Messrs. R. and T. Beck, of Cornhill, kindly supplied the microscopes for the evening. The buildings of the Society are being pushed forward at a rapid rate; and it is probable that the large new meeting-room, the need for which was very evident on Monday evening, will be ready for the reception of the Society during the present session. At the meeting on the 11th inst., amongst other communications, Dr. C. Theodore Williams will read the notes of a case of bronchiectasis treated by paracentesis.

#### MR. ANTHONY TROLLOPE.

SHORTLY after the publication of our last report a decided change for the worse took place in Mr. Anthony Trollope's condition. He had made great progress towards recovery during the week, and there was every hope of a speedy termination of his illness. On Saturday, however, he became drowsy and apathetic, and it was only too evident that further changes were taking place in the structures of the brain. On Sunday he was quite unconscious, and was unable to take nourishment of any kind; the heart's action was feeble and irregular, and it was with difficulty that the strength was maintained by suppositories of peptones, and other means. On Tuesday there was a sudden rise of temperature, and it was found that there was congestion of both lungs. Mr. Trollope died on Wednesday evening at six o'clock, there being no return of consciousness.

#### EFFECTS OF DIET ON LIABILITY TO INFECTION.

PROFESSOR FESER of Munich has been making experiments on animals with a view to establishing the connexion which exists between diet and liability to infection. In the trials he has made on rats inoculated with the poison of cattle distemper, he demonstrated the fact that the animals which had been fed on vegetable diet were quickly attacked by the disease, while those which had been fed exclusively on meat resisted the effects of the inoculation. In recording this fact a leading journal in connexion with the continental leather trade attributes to the greater amount of vegetable diet in the shape of bread, beer, &c., taken by woolsorters between Saturday and Monday, the greater frequency of cases of outbreak and the aggravation of disease during that period.

#### "LATE HOURS."

IT is a mistake to both rise early and late take rest. The rising early is good as a habit of life, if it does not mean robbing nature of her opportunity to recruit the exhausted strength of brain and body by prolonging sleep when that necessary luxury is at length enjoyed. There would appear to be some need of remonstrance on this score. The fashion of the day favours early rising and the manly "tub"; but those who rise early have, for the most part, sat up pro-

digiously late, and the tub is chiefly appreciated because it rouses the system, and makes it feel—and feelings are very deceptive—strong and vigorous. This is burning the candle at both ends. If we must sit up half the night, it would be better to sleep half the day than to rise betimes and go in for arduous labour after insufficient rest. Early rising is not good, but harmful, without early resting.

#### MR. FAWCETT.

WE have received the following authentic particulars of the illness of Mr. Fawcett. The first signs of ill-health revealed themselves on Nov. 23rd. On the 28th the distinguished invalid was seen by Dr. Andrew Clark, when a diphtheritic exudation was discovered on the left tonsil and uvula. The patches disappeared on Dec. 2nd, but returned next day, and lasted for a few days longer, accompanied with slight erysipelas of the face. There were from the very first symptoms calculated to raise suspicions of the presence of typhoid fever—e.g., looseness of the bowels, with typhoid-looking motions. The medical attendants, however, were not in a position to state positively that typhoid existed until Dec. 2nd. The symptoms of both diseases were modified by their co-existence. The enlargement of the cervical glands usual in diphtheria was absent. Especially noteworthy was the irregular form of the enteric symptoms. The pulse never exceeded 104; the temperature, ranging from 102° to 103·8°, at no period of the disease showed the typical typhoid curve; and the nervous disturbance was excessive in proportion to the vascular excitement. Mr. Fawcett cannot yet be said to be out of danger, but we are glad to state that his condition is, at the time of our going to press, reassuring.

#### M'GILL COLLEGE MEDICAL FACULTY.

AT the commencement of the current session of the above well-known Canadian College, the fiftieth anniversary of its foundation was celebrated. The introductory address was given by Dr. R. P. Howard, Dean of the Faculty, in the course of which he sketched the rise and progress of the university, of which all the medical graduates are Canadians. He gave a history of the first lecturers in the school, and paid a warm tribute of praise to the principal of the university (since 1855), Mr. J. W. Dawson, who had always taken a warm interest in the medical faculty. The main part of his address was, however, devoted to a memoir of the late Dr. G. Campbell, Dean of the Faculty in 1860, who died in Edinburgh when on a visit early in the present year. The brochure which contains the address is illustrated by a portrait of the lamented physician, who was as much esteemed by the Canadian people as by the College with which he had been so closely bound. The pamphlet contains also a full report of the speeches delivered at the banquet to celebrate the opening of the fiftieth session.

#### THE REGISTRATION SYSTEM AND IRREGULAR PRACTICE IN LEEDS.

A JURY, after inquiry into the cause of death of a little girl, aged four years, who had been ill a month and had no other medical attendance than that of an unqualified practitioner named Bowens, found death to have resulted from natural causes, but advised that the facts be brought under the notice of the Registrar-General. The facts which came to light were very serious, and to the effect that Bowens gave a letter about the cause of death which, on being taken to the deputy registrar, was pronounced by him "rather an irregular certificate," but "to save bother" he said he would give a certificate for burial. If registrars and the registration system exist to facilitate funerals and "to save bother,"

the action of the assistant registrar here is proper, but if not, we can only hope that the Registrar-General will take the recommendation of the jury into very serious consideration.

#### OLIVER WENDELL HOLMES.

WE learn with mingled feelings of pleasure and regret that Dr. Holmes has resigned the Chair of Anatomy in Harvard University—regret that he has felt it necessary to sever the connexion which has lasted thirty-five years, and which has been alike honourable to himself and beneficial to the medical profession throughout America, and pleasure when we consider the reasons which have led to his retirement. He has resigned in order that he may have more time to devote to literature, and thus increase the debt which we on this side of "the pond" already owe him for many an hour's entertainment. He has done more perhaps than any other contemporary American writer to amuse and instruct us. His poems possess humour, pathos, and grace; and in his prose, in addition to scholarly lore, he displays a minute knowledge of, and keen interest in, the human nature and stirring life around him. Of his novels (as distinguished from the more properly humorous books as the "Autocrat" and "The Professor at the Breakfast-table"), "Elsie Venner" is the most popular in England. The strangeness of the general conception, the unfamiliar hereditary curse, and the common human life through which the heroine steals, make up a novel unique and powerful in character. Another point on which we may congratulate ourselves is that Dr. Holmes writes English.

#### OBSTETRIC CONTRACTS.

NOTWITHSTANDING some decisions to the contrary, it is very unsafe to assume that where a medical man is engaged to attend an obstetric patient, and is not sent for, he may recover his fee in a County Court. Mr. G. H. Thurston has just failed to do so in the County Court at Barnet. He had been engaged to attend the case, which was expected in the end of August, but did not occur till the 18th of October. This is bad law in our opinion, and worse judgment. It must be supposed that Mr. Thurston's arrangements were restricted for two months by consideration for this patient—a fact which is disregarded in the judgment. We cannot believe that County Court judges who consider what is involved in a medical man making light of obstetric engagements will approve the decision of the judge in Mr. Thurston's case.

#### THE BRADSHAW LECTURE AT THE COLLEGE OF SURGEONS.

SIR JAMES PAGET, Bart., late President of the Royal College of Surgeons, will deliver the Bradshaw Lecture, "On some Rare and New Diseases," to be illustrated by the contents of the Museum, on Wednesday, the 13th inst., at 3 o'clock (not 4 o'clock, the usual lecture hour), in the theatre of the College. This lecture was founded by the widow of the late Dr. William Woods Bradshaw, F.R.C.S., sometime the Mayor of Reading, who bequeathed £1000 for that purpose, and a similar amount to the Royal College of Physicians.

#### SMALL-POX AT THE CAPE.

THE account of the panic at Uitenhage and other places and of an isolated case of an old Kaffir dying, without anyone to "watch" him, creeping out of his hut to die, and then being cremated with his hut by a sanitary deputation, is painful reading. Personal liberty and public business are very lightly regarded. The owners of steamships, especially Messrs. Donald Currie & Co., are coming in for severe censure, and are denounced as the cause of all the cases in the eastern

provinces by acting as carriers of infection from Cape Town. Everything is done, or rather proposed, by vigilance committees. But one thing that would be worth all the rest is very inadequately applied. If half the money that is being spent were applied to the extending and perfecting of vaccination and revaccination the results would be more satisfactory.

#### SIR THOMAS WATSON.

THE report as to the condition of Sir Thomas Watson is that he still survives and retains consciousness, but with gradually falling temperature and failing pulse. Her Majesty the Queen has telegraphed a kind message of inquiry.

#### PORRO'S OPERATION.

WE learn that the patient upon whom Dr. Godson performed this operation on November 27th, as noticed in our last issue, has up to the present time progressed uninterruptedly, and there is now every prospect of her recovery. The child is also quite well.

DR. LOCKHART ROBERTSON and Dr. CRICHTON BROWNE, the Lord Chancellor's Visitors in Lunacy, were officially present at the opening of the Royal Courts of Justice by Her Majesty the Queen on the 4th inst. The following members of the profession were also present:—Sir James and Lady Paget, Sir George Barrows, Sir Henry Thompson, Sir William Muir, Mr. Spencer Wells, President of the Royal College of Surgeons, Professor W. H. and Mrs. Flower, Professor Huxley, Professor J. Marshall, and Mr. Francis Mason, President of the London Medical Society.

DR. SAMUEL WHITE THAYER, Emeritus Professor of Anatomy in the University of Vermont, U.S.A., died on the 14th ult., aged sixty-five. In 1854 Dr. Thayer was elected to the chair of the Theory and Practice of Medicine in the university, and was subsequently transferred to the chair of Anatomy. During the war of the Rebellion he was appointed Surgeon-General of Vermont.

WE understand that the late Dr. Peacock has left a bequest sufficient to establish a scholarship in St. Thomas's Hospital medical school, of the value of forty guineas. The scholarship will be tenable for two years on the same terms as those of the "Musgrove Scholarship," and will bear the title of the "Peacock Scholarship."

THE total number of cases of yellow fever at Pensacola, U.S.A., is stated to have been 2330, with 191 deaths—a remarkably low rate of mortality. The epidemic appears to have entirely ceased.

## Public Health and Poor Law.

### LOCAL GOVERNMENT DEPARTMENT.

#### REPORTS OF INSPECTORS TO THE MEDICAL DEPARTMENT OF THE LOCAL GOVERNMENT BOARD.

*St. Helen's*, an urban sanitary district on the south-western limits of the Lancashire coal-fields, and having a population of nearly 60,000, has for many years past exhibited a considerable mortality from fever, the disease in question being almost invariably enteric fever. Locally, this special fatality is in great part attributed to the extent to which the atmosphere is polluted by the chemical works and by heaps of alkali waste, conditions which, it is alleged, cause diseases such as enteric fever to assume a malignant type. Mr. Spear,

who has visited the borough on behalf of the Local Government Board, discusses this question; but it is quite evident that the more recent prevalences of fever do not bear out the contention, a large number of mild attacks having occurred during their course. On the other hand, conditions well known to affect health injuriously, and to be either directly or indirectly associated with the prevalence of enteric fever, prevail to an extent which must be regarded as amply sufficing to explain the mortality which came to be inquired into. The house accommodation of the working classes, who almost exclusively make up the population, is generally unsatisfactory; the older property is badly built on insufficient space, and the newer property has suffered much at the hands of speculative builders. The midden-prives are of the most objectionable sort, and they consist for the most part of deep, wet, and foul pits; scavenging, too, is neglected. The main sewer is a brook, many of the tributary sewers are defective and are admittedly leaky throughout their entire length, the subsoil thus becoming polluted with filth. Cellars and basement rooms are at times provided with sinks communicating directly with the sewers, and although disconnexion is now insisted on, yet the local drainage arrangements admit of the yards being more or less flooded with slop water. Fortunately a good public water service is available and the shallow wells in use are but few in number. In short, it is quite evident that so many ordinary causes of preventable disease obtain in St. Helen's that the corporation has ample work in prospect for many years to come. There are certain local difficulties which have hitherto interfered with the adoption of any proper system of sewage disposal, and the absence of such a system has in its turn hindered the construction of proper sewers in the town. But apart from these works there is much that can be done to improve the health of the district, and it is specially important that the conditions of house-drainage and of excrement and refuse disposal should be dealt with in such a way as to ensure their permanent improvement. This end is specially held in view in the recommendations which are addressed to the sanitary authority at the end of the official report.

#### REPORTS OF MEDICAL OFFICERS OF HEALTH.

*Birkenhead*.—According to Mr. Vacher's annual report for 1881 the population of this borough at the last census was 84,006; the birth-rate has been 36.9 and the death-rate 19.7 per 1000. The latter rate, though falling short of that which sanitary administration, even in large boroughs, must aim at, is unquestionably satisfactory, and compares favourably with that of the large towns and cities of England. The infantile mortality of a district has always been regarded as one of the best tests of its local sanitary circumstances, and it is, hence, further satisfactory to note that whereas the mortality under one year of age was 14.0 per cent. for the large towns and cities, it was in the somewhat populous borough of Birkenhead only 12.8—namely, less than that for England and Wales as a whole, the rate for that portion of the United Kingdom being 13.0 per cent. Two outbreaks of typhus are discussed by Mr. Vacher, and, in connexion with these, he adverts, amongst other things, to the need both for notification of infectious diseases and for the power to remove patients to hospitals without the consent of their friends, whenever such isolation as will prevent the spread of infection cannot be carried out. The first want has now been met by the Birkenhead Corporation Act, 1881; the latter can only be fully met by fresh legislation, and it becomes doubtful how far the public are prepared to see Parliament grant such powers, however desirable they may be in the interests of public health. Some magistrates have, in isolated cases, decided that since the Public Health Act, 1875, has reference to the health of the community, rather than to the welfare of the individual, action can be taken under section 124 in the sense desired by Mr. Vacher, and we are not aware that when this has been done any appeal has been made against the decision. The borough fever hospital, one of the earliest provided, continues to do excellent work, and with a view of favouring its further usefulness, the sanitary authority very wisely allow any medical practitioner sending in cases to continue his attendance upon them. Delay, however, still occurs in effecting the removal of the sick, and extension of disease is necessarily the result. The tabular statements appended to the report show that a large amount of sanitary work is steadily in progress in the borough, and that Mr. Vacher's department maintains a

vigilant eye over all that pertains to the health of the inhabitants.

**Hull.**—During the year 1881 the deaths in the borough of Hull amounted to 23 per 1000, and the births to an annual rate of 36 per 1000, the population being estimated at 155,160. The deaths from zymotic diseases were exceptionally numerous, as many as 934 being registered as due to one or other of the seven principal zymotics, or at the high rate of 6 per 1000. This large death-rate was in the main caused by the occurrence of 682 scarlet fever deaths, as opposed to an annual average for the preceding fourteen years of 152 such deaths. The extensive epidemic which prevailed was recently reported on by Dr. Airy of the Local Government Board, and the principal facts concerning it are recapitulated by Dr. Mason in his annual report, special stress being laid on the fact that in the absence of a system of compulsory notification of infectious diseases the sanitary authority of a district like Hull is practically powerless to prevent the extension of such a disease as scarlet fever. In dealing with the subject of infantile diarrhoea Dr. Mason refers, amongst other points, to such questions as high temperature and so-called "atmospheric conditions," but it is perfectly evident that circumstances such as these are not alone responsible for the epidemic prevalence of this disease. We are informed that the frequent removal of night soil, the flushing and ventilation of the sewers and drains, and the cleansing of gullies, have been attended to by the sanitary authority; but other removable conditions of this infantile scourge must certainly exist, and we hope that before long something much more definite may be learnt as to the conditions leading to its causation, both in Hull and elsewhere. Efforts are evidently being made in this direction by Dr. Mason, who has both compiled an important series of tables localising the fatal attacks of this disease as well as other preventable ones, and prepared a map in which the various deaths are recorded by dots, differently coloured, according to the nature of the disease.

**Wolverhampton.**—In presenting his annual report for 1881, Mr. J. H. Love congratulates the town on its rapid progress from one of the most unhealthy districts in the kingdom to a position of average healthiness. Under the operation of the Artisans' Dwellings Improvement Act many fever dens have been swept away, and wide streets have replaced narrow and ill-ventilated alleys; a public mortuary has been provided; deep ash-pits have been filled in; many privies have been converted into pan-closets; improvement in the scavenging of house refuse is in progress; and the erection of a hospital for infectious diseases is about to be carried out. But a beginning has only been made in the removal of dwellings and lanes, which by obstructing light and proper movement of air, are still a grave cause of unhealthiness; typhoid fever is traced to insanitary surroundings; and infantile diarrhoea is an important element in the death-rate. The total death-rate for the borough is 21 per 1000 living, and phthisis, with certain other lung affections, contribute to it in a marked degree, the rate of mortality depending very largely, as is shown in a carefully prepared table, on the prevailing meteorological conditions. In this connexion, it must, however, be noted that Wolverhampton lies on a clay subsoil, and that it is peculiarly exposed to the influence of east winds.

**Presteigne.**—We regret that by error we attributed the report on Presteigne to Dr. Covernton. Presteigne is within that portion of the Knighton rural district for which Dr. R. Harding acts as medical officer of health, and the report was prepared by him.

The enactment contained in the 90th section of the Public Health Act, 1875—that, namely, which deals with houses let in lodgings—is declared by the Local Government Board to be in force within the city of Gloucester.

## VITAL STATISTICS.

### HEALTH OF ENGLISH TOWNS.

In twenty-eight of the largest English towns 5729 births and 3615 deaths were registered during the week ending 2nd inst. The annual death-rate in these towns, which had steadily increased in the four preceding weeks, from 21·3 to 24·2 per 1000, fell again last week to 22·3. During the first nine weeks of the current quarter the death-rate in these towns averaged 21·7 per 1000, against 22·0 and 21·2 in

the corresponding quarters of 1880 and 1881. The lowest death-rates in these towns last week were 14·7 in Bolton, 14·9 in Portsmouth, and 17·4 in Leicester. The rates in the other towns ranged upwards to 27·9 in Halifax, 28·1 in Liverpool, and 28·6 in Newcastle-upon-Tyne. The deaths referred to the principal zymotic diseases in the twenty-eight towns declined to 427, and were fewer than in any previous week of this year; 115 resulted from measles, 111 from scarlet fever, 85 from "fever" (principally enteric), 49 from whooping-cough, 35 from diarrhoea, 22 from diphtheria, and 10 from small-pox. The lowest death-rates from these zymotic diseases occurred in Bradford and Norwich, and the highest in Sunderland, Cardiff, and Halifax. Measles caused the highest death-rates in Cardiff and Sunderland; scarlet fever in Oldham, Halifax, and Sheffield; whooping-cough in Halifax and Preston; and "fever" in Portsmouth, Halifax, Newcastle-upon-Tyne, and Liverpool. No fewer than 18 of the 22 deaths from diphtheria in the twenty-eight towns occurred in London. Small-pox caused 5 deaths in London, 4 in Newcastle-upon-Tyne, and 1 in Nottingham. The number of small-pox patients in the metropolitan asylum hospitals, which had been 73 and 68 on the two preceding Saturdays, was 70 at the end of last week; 15 new cases of small-pox were admitted to these hospitals during the week, against 16 and 7 in the two previous weeks. The deaths referred to diseases of the respiratory organs in London, which had been 330, 345, and 411 in the three preceding weeks, further rose to 424 last week; this number was, however, 69 below the corrected weekly average. The causes of 109, or 3·0 per cent., of the deaths in the twenty-eight towns last week were not certified either by a registered medical practitioner or by a coroner. All the causes of death were duly certified in Portsmouth, Norwich, Plymouth, Derby, and Blackburn. The proportions of uncertified deaths were largest in Liverpool, Salford, Oldham, Halifax, and Sunderland.

### HEALTH OF SCOTCH TOWNS.

The annual death-rate in the eight Scotch towns, which had been equal to 25·8 and 24·3 per 1000 in the two preceding weeks, was 24·8 in the week ending the 2nd inst., and exceeded by 2·0 the mean rate last week in the twenty-eight English towns. The deaths referred to the principal zymotic diseases in these Scotch towns, which had been 98 and 78 in the two previous weeks, rose again to 88 last week, and were equal to an annual rate of 3·8 per 1000—1·2 above the rate from the same diseases in the English towns. The fatal cases of whooping-cough numbered 21 last week, of which 10 occurred in Glasgow, and 3 both in Dundee and Aberdeen. The 19 deaths from diphtheria were within 1 of the number in the previous week, and included 11 in Glasgow and 8 in Dundee. The 16 deaths attributed to diarrhoea were 6 above the number in the corresponding week of last year. The 12 deaths referred to "fever" exceeded those in the previous week by 6; 7 occurred in Glasgow, and 2 in Leith. The fatal cases of scarlet fever, which had been 18 in the previous week, fell to 12 last week, of which 8 were returned in Glasgow, and 2 both in Edinburgh and Paisley. Of the 8 deaths from measles 7 occurred in Glasgow. The deaths referred to acute diseases of the lungs in the eight towns, which had been 172 and 167 in the two preceding weeks, further declined to 139 last week, but were 36 below the number in the corresponding week of last year. The causes of 118, or 23 per cent., of the deaths registered in the eight towns last week were not certified.

### HEALTH OF DUBLIN.

The annual rate of mortality in Dublin, which had been equal to 26·1 and 29·2 per 1000 in the two preceding weeks, declined to 25·6 in the week ending the 2nd inst. During the first nine weeks, however, of the current quarter the death-rate in the city averaged 24·3 per 1000, against 20·5 in London and 19·3 in Edinburgh. The 171 deaths in Dublin last week showed a decline of 24 from the number in the previous week, and included 14 which were referred to the principal zymotic diseases, against 11 and 14 in the two previous weeks. These 14 deaths included 6 which were referred to "fever," 5 to whooping-cough, 2 to diphtheria, 1 to diarrhoea, and not one either to small-pox, measles, or scarlet fever. The death-rate from these zymotic diseases was equal to 2·1 per 1000, while the rate from the same diseases last week was 2·9 in London and 1·6 in Edinburgh. The 6 deaths referred to "fever," in Dublin last

corresponded with the number in the previous week, were equal to a rate considerably exceeding the mean last week in the principal English and Scotch towns. 5 deaths from whooping-cough showed a further increase upon recent weekly numbers. The 2 fatal cases of thieria raised the number recorded during the past four weeks to 4. The deaths of infants showed a marked decline week, whereas those of elderly persons showed a further decrease.

## HEALTH MATTERS GENERALLY AT HOME AND ABROAD.

### SANITATION AT DETROIT, U.S.A.

The first annual report issued by the Board of Health for the city of Detroit, in the State of Michigan, U.S.A., has been prepared with much care by Dr. O. W. Wright, the health officer. A description is given of the laws creating the health department, and of the organisation for administrative work. The sewerage and the system of house-drainage are discussed and the needed remedial measures pointed out. The slaughterhouses come in for a large share of condemnation, and the necessity for a public abattoir is pointed out. In dealing with the subject of the prevention of zymotic diseases, we note that the inhabitants of the city are likely to meet with much the same difficulties as have been met in our own metropolis since the publication of the report on the Influence of the Fulham Small-pox Hospital. Detroit sends its small-pox patients to Grosse Pointe, 11 miles apart from the fear of a spread of infection during the winter there, it appears that the inhabitants of that suburb are so hostile to the building as to have threatened to destroy it by fire. In view of these circumstances Dr. Wright makes a suggestion as to the construction in the city of a "Flame-Ventilated Small-pox Hospital," in some respects similar to the proposals which we considered in an article last week's issue. We doubt, however, whether, in view of the fact that the windows are to be made to open, Dr. Wright's anticipations as to the whole current of ward-air being carried up a shaft fitted with gas-jets will be realised. The report also contains two interesting chapters on the ice and milk supply of the city, and on the possibility of infection being conveyed by means of these two articles. Indeed, if the first issue may be taken as a sample of those which are to follow, there is every prospect that a new and valuable series of documents relating to questions of public health has been inaugurated.

### THE WATER-SUPPLY OF MELBOURNE.

Works of considerable magnitude are in progress with a view to an improvement in the water-supply of Melbourne. When they are completed the spring waters from the Plenty ranges will be conveyed direct to that city by means of a series of aqueducts and altered watercourses, which will admit of a daily flow of about 100,000,000 gallons. At present much of the water that will become available for domestic purposes becomes seriously polluted whilst passing through a flat, low-lying country, but as soon as labour can be spared from the works in progress at Wallaby creek in the mountains, the water will, on joining the main bed of the Plenty river, be diverted by means of a dam into a clear water-channel over four miles in length, and exhibiting several artificial cascades in its course, and from this the supply to the water-mains will pass. Our colonial brethren are carrying out a work which will largely tend to the future health and prosperity of their city, and in its execution they are availing themselves of the experience which has been obtained in connexion with similar works both in their own and other countries. The possibility of a water famine, such as has been anticipated in the past, will soon be effectually removed, and, judging from a description of the works, the future supply will be one to which, so far as its source is concerned, no suspicion of unwholesomeness can be attached.

### THE ARTISANS' DWELLINGS ACT AT ABERDEEN.

Dr. Beveridge, chairman of the Public Health Committee, has given notice that at the next meeting of the Town Council he will move "That it be remitted to the Public Health Committee to inquire into the expediency of applying the provisions of the Artisans' Dwellings Improvements (Scotland) Act to any portion of the city, and to report.

## THE SERVICES.

**ARMY MEDICAL DEPARTMENT.**—Surgeon-Major William Ashton, M.B., to be Brigade Surgeon, vice G. L. Hinde, retired upon temporary half-pay; Surgeon-Major George Whitla to be Brigade Surgeon, vice N. Ffolliott, granted retired pay; Surgeon-Major Edward Footner, M.B., has been granted retired pay with the honorary rank of Brigade Surgeon; Surgeon-Major Kenneth William Cumming, M.D., has been granted retired pay with the honorary rank of Brigade Surgeon.

**ARTILLERY VOLUNTEERS.**—1st Fife-shire: William Chalmers-Cowan, gent., to be Acting Surgeon.—2nd Middlesex: Surgeon John Wickham Barnes is granted the honorary rank of Surgeon-Major.—1st Norfolk: George Henry Cressey, gent., to be Acting Surgeon.

**RIFLE VOLUNTEERS.**—1st Isle of Wight: Surgeon George Henry Roqué Dabbs, M.D.—22nd Lancashire: Robert Lancelot Sparrow, Gent., to be Acting Surgeon.—2nd Middlesex (Central London Rangers): Acting Surgeon James Hill, M.D., resigns his appointment.—3rd Volunteer Battalion, the Prince Albert's (Somersetshire Light Infantry): Acting Surgeon Frederick James Brennand resigns his appointment.

**ADMIRALTY.**—The following appointments have been made:—Surgeon Alfred T. Corrie to the *Pembroke* (complement incomplete); Surgeon John O'Callaghan to the *Cambridge*, vice Alfred T. Corrie; John M. Phillips, M.D., has been appointed Surgeon and Agent at St. Dogmael's and Aberforth, vice Mr. Henry C. Noott, deceased; Surgeon Edward H. Williams, to the *Asia*, vice James Bradley (appointment of Surgeon Charles W. Sharples cancelled); Fleet Surgeon William D. Longfield, to the *Himalaya*; Fleet Surgeon Samuel Bamfield, to the *Indus*, vice Longfield; Staff Surgeon Herbert M. Ellis, to the *Pegasus*; Staff Surgeon John Lambert, to the *Lion*, vice Bamfield; Surgeon Edward R. Mulock, to the *Himalaya*; Surgeon Henry A. W. Richardson, to the Devonport Dockyard for service at Keyham, vice Mulock.

## GLASGOW ROYAL INFIRMARY SCHOOL OF MEDICINE.

Six years ago the managers of the Glasgow Royal Infirmary, considering a medical school to be essential to the success and proper utilisation of the institution under their care, obtained from Government a supplementary charter, under which they appointed lecturers in the several subjects of the medical curriculum. The accommodation at first provided for the lecturers was of a temporary nature and far from satisfactory, and as the school increased in numbers the managers felt justified in appealing to the public for funds. Donations were obtained of sufficient amount to render possible the erection of buildings worthy of the infirmary and the city. These are now completed. The buildings are of stone, one in the Italian style of architecture and one situated behind the infirmary proper. The plans were very carefully prepared to meet the requirements of scientific medical teaching. The anatomical department is particularly well arranged. The dissecting-room measures 67 ft. by 25 ft., and is 24 ft. high; it is entirely lighted from the north, the roof being of the form known as the "spinning factory roof," there being also long side windows. The roof has an open ridge, covered with perforated zinc, which secures very free ventilation. Around the room are arranged desks, in which are placed mounted anatomical specimens, in order that students may study them at leisure. Opening out of the dissecting-room is a lavatory, supplied with hot and cold water, and fitted with wash-basins, with marble tops, boxes for appliances, and other conveniences, so as to render the students as comfortable as possible. The anatomical lecture-room is seated for 150 students, the seats being arranged in a semicircle; it is lighted chiefly from the roof, but also from the north and east. The lighting and heating are especially satisfactory in this room. The anatomical museum has also both roof and side light; it is lined with cases with glass fronts, which are well stocked with models and the like, and in the centre of the floor is a large counter case, on which are some fine wax casts. The osteology-room is furnished

with baize-covered tables for the students to sit at and read, and on the tables are fixed glass cases containing bones on which the attachment of muscles is clearly displayed. For the study of physiology an excellent laboratory and convenient lecture-room are provided, and by a simple arrangement of the partition between these they can be thrown into one, so as to make the whole of the side light available for microscopic work. The laboratory is supplied with an excellent collection of physiological apparatus, part of it being purchased by means of a donation from Dr. Henry Muirhead, the rest being the property of the lecturer. The chemistry department consists of a well-lighted and admirably fitted up lecture-room, the table having been specially constructed so as to give the lecturer a free supply of gas and water. Adjoining this is a laboratory capable of accommodating about forty students; it is quite a model of what such an establishment should be, the arrangements for gas, water, light, and test appliances being the best that could be devised. A new feature (as compared with other medical schools in this country) is a toxicological laboratory for teaching the testing of poisons. Much thought has been expended by the lecturer on medical jurisprudence in the arrangement of this department, and there is no doubt it will prove of much use as an aid to the study of an important branch of medical education. Near this is a room, at present unoccupied, but intended for a surgical museum and work-room in connexion with the surgery lectureship. A large and comfortable lecture-room for the other classes is situated on the ground floor, and lighted by an ingenious arrangement of roof and wall light, so as to secure a steady light without glare. Private rooms for the lecturers have been provided, and a private lavatory supplied with hot and cold water. One of the features of the school is a students' room, with lavatory attached; here, in the intervals of the classes, the students may smoke, read, or chat. It will no doubt be much appreciated by those for whose comfort it is intended. These buildings were formally opened and inaugurated on Wednesday evening, Nov. 1st, by a brilliant conversation, which was very well attended by the medical profession in Glasgow and neighbourhood.

## Correspondence.

"Audi alteram partem."

### THE OPPOSITION OF THE SCOTTISH UNIVERSITIES TO MEDICAL LEGISLATION.

To the Editor of THE LANCET.

SIR,—Will you kindly publish the following letter of Dr. Gairdner's, in reference to his attitude towards proposals for legislation for the creation of three conjoint boards, in place of the nineteen existing bodies in Schedule A of the Medical Act.

Yours truly,

Highbury, December, 1892.

J. G. GLOVER.

"Dear Dr. Glover,—In the only detailed report I have seen of the recent deputation from the British Medical Association to Lord Carlingford and Mr. Mundella (*Scotsman*, Nov. 23rd), I find you referring to my name along with that of Professor Turner, and it would almost appear as if our supposed assent to the principle of a joint board was to be made a starting-point for the further assumption that the opinion of Scotland, or of the Scottish universities, might be reckoned upon in future as favourable to some modification of that principle. Were it not for this suggestion, which appears both in your own remarks and in the leading article in THE LANCET of to-day, I might be content to leave Professor Turner's opinion to be read in his separate memorandum (F) subjoined to the report of the Royal Commission, and my own in my evidence, which you will find not at all in accordance with the views you attribute to me, see especially Nos. 4759-62, 4765-68, 4770-86. It is not my object at present to argue the matter; but as Lord Carlingford and Mr. Mundella, as well as others, may have been misled, I will ask you to secure the insertion of this letter, along with any report that may appear in THE LANCET of the proceedings of the deputation.

"I am, Sir, yours, &c.,

"W. T. GAIRDNER.

"Nov. 25th, 1892."

\* \* The subject of Dr. Gairdner's letter is noticed in another column.—ED. L.

### "PICRIC ACID AND SUGAR TESTING."

To the Editor of THE LANCET.

SIR,—It would be a waste of my time and of your space to discuss the question whether my discovery or Dr. Pavy's criticism bears the impress of having been the more "hastily communicated." Upon this comparatively unimportant question the following reply to Dr. Pavy's letter may perhaps assist your readers to form their own judgment.

Dr. Pavy's statement of his belief that it "would be an absolute misfortune for a more sensitive test than the cupric test to be introduced into general use," would have appeared to me quite unintelligible if I had not lately had the benefit of a few minutes' conversation with him, during which he expressed his fear that a test so sensitive as to reveal the presence of sugar in normal urine would cause practitioners to mistake a physiological condition for diabetes. But surely the true way to obviate so serious an error is not to endeavour to keep the profession in ignorance of the easily demonstrated fact that sugar is a normal constituent of the urine; but to make it generally known, and to supply them with the simplest and surest means of verifying it for themselves. But, says Dr. Pavy, the alkaline sulphides cause the same reaction as grape sugar with picric acid and potash. Granted.

The question, then, is, Are alkaline sulphides always, or often, present in normal urine? There is no known test for sugar which may not give a similar reaction with some other material than sugar. Dr. Pavy, in his treatise on Diabetes (p. 16) states that chloroform, uric acid, and cellulose may cause a precipitate of suboxide in Fehling's cupric solution. To be forewarned of these possible fallacies is to be forearmed against them. But Dr. Pavy, in his letter, goes on to state that "sulphides of ammonium and potassium are capable of being generated by boiling urine with potash." This, so far as regards normal urine, I am told by much better chemists than myself, is an improbability, and cannot be accepted on the mere *ipse dixit* even of so great an authority as Dr. Pavy. He further states "that a sulphide is actually produced by the action of potash upon healthy urine is shown by the well-known fallacy that Moore's or the liquor potassæ test is open to from the presence of a little lead." I confess that this statement surprises me not a little. It has often happened to me in boiling albuminous urine with liquor potassæ to find the liquid darkened, and a subsequent precipitate of sulphide of lead, the sulphur being a constituent part of the albumen and the lead an impurity of the potash; but I have never observed this change to occur in healthy urine; and since reading Dr. Pavy's letter I have repeated the experiment on normal urine with a negative result, while adding a solution of lead to the mixture.<sup>1</sup>

I have also repeated Dr. Pavy's experiment, which consists in forming an alkaline sulphide by boiling white wool with caustic potash. The liquid gives the same colour as grape sugar with picric acid. The addition of equal parts of this solution to healthy urine caused no appreciable change in the reaction with picric acid and potash. Then the question arises if a sulphide exists in the urine in a state to cause the reaction with picric acid, and so to interfere with the test for sugar, can the sulphide be detected by any other test? Obviously it can. On adding a few drops of the above-mentioned white wool product to healthy urine, and boiling with the addition of a minute quantity of lead solution, the mixture was soon blackened by the resulting plumbic sulphide. Again, on adding a few drops of Fehling's cupric solution to the mixture of the sulphide from white wool with normal urine, there was an abundant precipitate of cupric sulphide. The conclusion, then, is that normal urine contains no sulphides, nor any material convertible into sulphides by boiling with caustic potash, and that if from any exceptional condition sulphides are present, they may readily be detected and separated by well-known and very simple methods.

In testing for sugar in albuminous urine, the albumen may readily be removed by boiling and subsequent filtration before applying the picric acid and potash test. That this pre-

<sup>1</sup> Dr. Wm. Roberts says: "It was never found that liquor potassæ containing lead produced a dark-brown colouration with non-albuminous urines, provided, of course, that they were sugar free" (*A Practical Treatise on Urinary and Renal Diseases*, 2nd edition, p. 178).

nary treatment is sometimes necessary in testing for in albuminous urine, even by Fehling's solution, is ed by an eminent writer, whose authority will not be stioned by Dr. Pavy.<sup>2</sup> No one who is acquainted with Pavy's ammoniated cupric test can doubt that it is an et and admirable method of quantitative analysis; but it uires a more complicated apparatus and a greater amount manipulative skill than are possessed by the majority of ititioners, who would gladly avail themselves of some pler method, which, even if it were less scientifically rate, might for every-day use be of more practical e. Such a quantitative test, notwithstanding Dr. y's regretfully expressed unfavourable predictions, will abably result from the "happy accident" before red- ed to.

ly son having had his attention directed to the question alkaline sulphides in normal urine, has made some eriments, the results of which are recorded in the owing letter.

I am, Sir, yours faithfully,

ville-row, Dec. 5th, 1882.

GEORGE JOHNSON.

\* Want of space compels us to hold over the letter of . Stillingfleet Johnson, referred to above.—ED. L.

## PHTHISIS, ITS ETIOLOGY AND TREATMENT.

To the Editor of THE LANCET.

SIR,—May I beg you will have the kindness to afford me ficient space in THE LANCET to make a few remarks a form of treatment of phthisis which has suggested itself me from the start-point of the researches of R. Koch of rlin, in whose hands the experimental method has resulted proving that tuberculosis is, in reality, a parasitic disease of e internal animal organs, and that the parasite is a bacillus tinguishable from all other bacilli by its microphytic and er features. In his letter to *The Times* of April 22nd last, e vast importance of this discovery was fully illustrated in , usual felicitous manner by Professor Tyndall; and reflect- g on this discovery, and reasoning from analogy, the thought rurred to me that a means which in my hands had been and of signal advantage in the treatment of leprosy in dia might, assuming the truth of Koch's discovery, be ually useful if applied to that of tubercle; for I had many ars ago ceased to entertain the least doubt that the *foes et igo* of leprosy was a microphytic one, and therefore to be ach by a means having for its object the destruction of at low form of organic life. The space to which I am mitted here will not admit of more than a brief *résumé* of the ews I advanced in my communication to *The Times* June 8th. Speaking of the light thus thrown on the inta- te nature of tuberculosis through Koch's painstaking e researches, and of the "enormous superficial unlikeness," rged by Professor Tyndall, that existed between the eru- ve diseases and tuberculosis, I endeavoured to enforce e view that, although such a dissimilarity did appear eat, it was not in reality nearly so marked as that which xisted between them and leprosy—a disease which I firmed must be included in a like category—dependent, ke them, on the growth within the animal body of a e disease-producing bacillus. Hence I was led to suggest that eans which I had found of signal efficacy in the treat- ment of leprosy should be had recourse to in that of the indred malady tuberculosis, the agent employed being car- bolic acid in intimate union with the vapour of water at a high temperature. Thus employed the acid is, so to speak, atomised, losing thereby much of its irritant prop- erties, and being brought into contact with the body of the patient, confined in a suitable vapour-proof apparatus, cutaneous absorption necessarily follows, thus saturating every tissue of the body with an agent in no way in- jurious to life when thus employed, though destruc- tive of the microphytic life from which the disease has its source. Were the treatment of disease by the cuta- neous absorption of medicinal agents a novel suggestion, or one involving the negation of physiological law, valid objection might well be taken against its application to that of tuberculosis. But it is not so; other forms of dis-

ease of a severe and an intractable type have been, and still are, successfully treated through the medium of cutaneous absorption.

Coming, then, to the subject I had in view in this communication, it occurred to me, as the outcome of the thought I have given to Koch's discovery, that seeing it has now been proved that the bacillus of tubercle is not a mere epi- phenomenon of tubercle, but its *vera causa*, one cannot fail to see in it the true source of those infective materials whose existence has hitherto been assumed by pathologists, and which, disseminated by means of the blood and lymph streams, call into being those structural lesions which characterise tubercle as occurring in man and the lower animals. In the presence therefore of such conclusive evidence, is it unreasonable, I would ask, to anticipate that, should the resources of nature and art, as now known to us, fail to supply us with an agent possessing properties adapted to the object of reaching and destroying the microphytic sources of tuberculosis in the deep-seated tissues of the body, such an agent may not yet be brought to light? That in carbolic acid we possess such an agent in the treatment of leprosy, it has been my endeavour to show, whilst at the same time suggesting its possible applicability to that of tubercle. But are our existing resources really so meagre as to leave us destitute of other therapeutic means fitted to subserve the teaching of pathology? Without presuming to answer such a question in the affirmative, it is yet incumbent on me to submit to the attention of the profession a means which I would suggest is worthy of an extended trial—I mean salicin. Our know- ledge of the action of this medicinal agent on the animal body, and of its reactions in disease, remains much as it was when communicated to the profession through the researches of Senator, Lehmann, and Miller. No doubt, in more recent years, additional light has been let in on the subject by other workers whose conclusions on the *rationale* of the action of salicin are, I presume to think, certainly suggestive of its being made applicable as a curative means to that family of diseases whose intimate nature and dependence on pathogenic germs the experi- mental method has placed beyond the reach of cavil or doubt. It is not in salicin, in its simple state, that such a result can be looked for, but in those changes which it most assuredly undergoes while circulating in the blood and lymph streams, where, subjected to the influences of the animal chemistry, it is transformed into agents whose destructive energy on microphytic life none can question. That the resultant of those changes is an acid body endowed with such qualities, abundant proof is not far to seek, though this is not the place to adduce it. Till very recently it was generally believed that this acid was salicylic—a view which is no longer tenable if it be proved, as very recently affirmed by Dr. Stewart of Edinburgh, and resting on experiments made by himself, that the acid is, in reality, the carbo- lic. Let this be as it may, be it carbo-lic or salicylic acid, both agents really belong to a like category, and are both equally available in the treatment of disease of microphytic origin—the former by the method suggested in my letter to *The Times*, the latter by the internal use of salicin, both agents leading to a like result—the destruction of pathogenic germs. But it is in salicin alone, and not in its compounds, that we must look for the realisation of this object—in its compounds no doubt, but only such as are fashioned in nature's labora- tory; and not in the chemist's. Because—and if space were permitted to me here it would be easy to show that the salicy- lates—comporting themselves as other neutral organic salts, undergo changes in the gastric fluids which involve the destruction of the specific properties of the acid base, while, at the same time, often reacting injuriously on the system by calling into existence symptoms which at times have led to fatal consequences. And, further, it is to be remembered that the success of the treatment is contingent alone on the persistent and the uninter- rupted use of the salicin; conditions which will be the more easily fulfilled since experiments have shown, notably those of Dr. Sydney Ringer, that, other things being equal, this substance can be taken in indefinite quantities and without inconvenience, which would be impossible in the case of the salicylates, even were they much less irritating than experience has shown them to be. The use of salicin must therefore be persistent and continuous in order to balance, so to speak, the equally constant elimination by the kidneys of the compound acids which it forms in the blood and lymph streams; and this, not for the purpose of

<sup>2</sup> The Nature and Treatment of Diabetes, by F. W. Pavy, M.D., F.R.S., 2nd edition, p. 17.

effecting tissue changes, but for that of destroying the organisms which are the source of those changes.

Let me conclude with the following brief record of a case of tubercular phthisis which has been subjected to the salicin treatment, that of a young man twenty-two years of age, in whom the disease had passed into its second stage when I first saw him a little over two months ago. Then the upper third of the left lung was involved in tubercular disorganisation, while in the apex of the right and subclavian region disease was present and seen in the dulness, increased vocal resonance, prolonged expiratory murmurs, and the compound râles never absent in like cases. For upwards of six weeks the salicin has been persistently used in association with phosphate of lime, with the result that now all disease has quite disappeared from the right lung, while the improvement in the left has been most gratifying. The cough, dyspnoea, and expectoration of mucopus have lost much of their former force, and he can now take exercise without being troubled with his former distressing dyspnoea. He sleeps well, there are no night-sweats, and his appetite is good. A week after commencing the salicin he increased 5 lb. in weight, and he is now stouter, stronger, and looking better than before he became the subject of disease. I need scarcely add that the usual auxiliary means were employed—cod-liver oil, medicated inhalations, &c.

I am, Sir, yours truly,

WILLIAM JOHNSTON, M.D.,

Northwich, Cheshire, Nov. 10th, 1882. Surgeon-General.

### BORACIC ACID IN DIPHTHERIA.

*To the Editor of THE LANCET.*

SIR,—I find in the report of the Clinical Society, published in THE LANCET of November 18th, a record by Dr. Goodhart, of six cases of diphtheria treated by the local application of borax or boracic acid, with an amount of success which had not as yet been established, as far as he knew. Dr. Goodhart says "both borax and boric acid have been occasionally in use as a topical application in diphtheria, doubtless, for a long time, but not, so far as is known, with any decided success." I regret to have to challenge Dr. Goodhart's statement as to the success of the remedy, and must refer him to my communication which appeared in THE LANCET of February 15th in this year, where I advocated the use of boracic acid as a specific in diphtheria, when resorted to in the early stages of the disease. During the past ten years I had exceptional opportunities of watching its effects in over a hundred cases of diphtheria, and more especially during the epidemic which occurred some few years ago in this district, and which the Editor of THE LANCET must well remember from the controversy we then had as to the number of deaths which occurred within the district. Upon that occasion I treated seventeen cases during one week with the boracic acid application—all recovered; and throughout the epidemic I lost one only—namely, a child four years old, who dropped dead whilst playing with its toys in bed some few days after all the symptoms of the disease had disappeared. During the same epidemic ten children of various ages died in the district, none of whom had been treated upon my plan. So great has been the success of the boracic acid treatment in diphtheria in this neighbourhood, that it is as well known as Fowler's solution is for ague; and I can safely state that there is more boracic acid used medicinally in this part of the country than in any county in England. Not that we have been troubled for some long time past with diphtheria, but the remedy is so well known that upon the advent of throat affection, irrespective of its nature, the public immediately resort to it.

Dr. Goodhart speaks of the application "loosening, dissolving, and preventing the reformation of membrane." From repeated experiments with the membrane placed in solutions of various strengths of boracic acid and glycerine at 100° F., I have not found any sign of its being dissolved after exposure to its action for twenty-four hours, therefore I venture to substitute the term detach for dissolve, used by Dr. Goodhart.

I am, Sir, yours, &c.,

T. D. HARRIES, F.R.C.S. Eng. (Exam.)

Aberystwith, Nov. 28th, 1882.

### "DEATHS AFTER ABDOMINAL OPERATIONS FROM HEART-CLOT."

*To the Editor of THE LANCET.*

SIR,—I have to thank a number of correspondents for suggestions and references, particularly Dr. Neale (author of the valuable "Digest"), for the only one which seems at present likely to be of practical use. I cannot, in the compass of a letter, enter into the question raised by Mr. Knowsley Thornton, nor do I think it necessary, for my recently published statistics show that abdominal operations do far better without Listerism than with it. Mr. Thornton's statements that the deaths of my cases were septic has no foundation whatever, and even if it had, when I turn to Mr. Wells's recently published books, as I was asked to do by Mr. Thornton, I find this remarkable contradiction of Mr. Thornton's assertion (at p. 224): "They [Lister's anti-septic plans] certainly have not brought me to the point of seeing no deaths from septicæmia, as promised by some of their enthusiastic promoters, nor have they advanced my success in operating beyond what was attained without it." With this sentence I entirely agree (save in its grammatical inaccuracy), and I think Mr. Thornton now stands alone in opposition to it. The experience of everyone, operators as well as patients, is that carbolic acid, even in very small doses, is very dangerous for feeble kidneys. I have heard that Mr. Thornton's own experience has been unfortunate in this direction. The form of death I see in these kidney cases is altogether different from the deaths hitherto recognised as occurring from septic poisoning, and I am not in the least prepared to accept Mr. Thornton's new device of "septic intoxication"; and his statement that I am afraid to admit a death from septicæmia is not correct, for, most unfortunately, I am undergoing this distressing experience as I write.

In conclusion, let me ask Mr. Thornton one question: Why is it that, with all the blessings of Listerism, operations are shirked in London? The patients come here, and are operated upon successfully without it. He is already in possession of the identification of a case of a huge and rapidly growing uterine myoma, which was under his own care in the Samaritan Hospital, the risk of operating upon which he declined. The patient came here and had the operation performed successfully, just nine weeks ago, and has gone home perfectly well; and this is by no means a solitary instance. If Listerism is such a royal road to surgical success, surely such incidents ought to occur in the converse way; it should be that I should refuse to do them, not using Listerism, and that Mr. Thornton should succeed with it.

I am, Sir, yours truly,

Birmingham, December, 1882.

LAWSON TAIT.

*To the Editor of THE LANCET.*

SIR,—Mr. Lawson Tait's note on this subject in THE LANCET of November 25th, calls attention to a subject of special importance to the surgeon. It is one to which my attention has been painfully attracted for several years, as Mr. Tait's has been now, ever since Mr. Doran demonstrated by a series of post-mortem examinations at the Samaritan Hospital that disease of the kidneys, unrecognised during life, had been at least a predisposing cause of death, in some cases the only cause. Two years ago, at one of the meetings of the Royal Medical and Chirurgical Society, I adverted to obscure disease of the kidney in these words:—"Now the importance of the matter consists in this—viz., that a patient with disease of the kidneys—say cirrhosis, as my patients had—is in a very unfavourable condition for any surgical procedure, and especially for such an operation as ovariectomy, and for the reason that she possesses very little power of elimination, so that the presence of effete matter in the blood in greater or less quantity is sure to provoke, sooner or later, serious symptoms, under which the patient too surely succumbs. And the worst part of the matter is this, that this condition is not indicated by sufficiently positive signs . . . I should be glad if any one would furnish us with an unfailing sign of the existence of this condition. For my part I should hesitate, if I did not actually refuse, to operate in such a case." Mr. Tait's

ards are a singularly close, though unconscious, repetition of these views, in which further experience has tended to affirm me.

A few months ago I removed a large fibroid (56 lb.) by dominal section, and the patient died in forty-eight hours, the rapid rise of pulse and temperature (this was as quickly lulced by the ice-cap), gradual suppression of urine, and progressive coma. The kidneys were in exactly the condition described by Mr. Tait. As in his case also, "the tails of the operation were quite satisfactory." Yet the examination of the urine, both before and after the operation, failed to appraise of this condition. A few weeks ago I performed another hysterectomy, and the patient died in twenty-five hours with the most complete suppression of urine. Within six hours the temperature had risen to 104°, and the pulse to 144 (closely resembling my use of hyperpyrexia from carbolic poisoning with suppression of urine). In this case the kidneys were large, pale, and fatty. Before operation the urine measured two pints and a half in twenty-four hours; there was no albumen; specific gravity 1032, and no sugar. Though not satisfied with the state of the urine, yet I did not suspect the kidney disease.

I could mention other cases, chiefly cirrhosis, in which the examination of the urine failed; but these will suffice as examples of two different forms of disease.

On the other hand, I have operated successfully where the urine has contained an abundance of albumen. The last case is the most striking. A single woman, aged thirty, was the subject of a large fibroid, which produced severe menorrhagia and profound anæmia, and exerted such pressure that the lower extremities were very oedematous; the urine contained as much as one-third of albumen, but was otherwise healthy. Within twelve hours after hysterectomy there was a mere trace of albumen, and in three days the oedema had disappeared. A similar series of events occurred in two cases of ovariectomy.

When Mr. Tait tells us that he has operated successfully in cases of Bright's disease, I feel inclined to look upon the statement as not sufficiently precise and to believe that there is an error somewhere, for my experience is so positively opposed to it. It is a remarkable fact that all my cases of true Bright's disease have occurred between the ages of forty and fifty-five, a period of life marked by singular fatality—so often attributed to "change of life"—in the female subject. If a woman lives to the age of sixty and presents a healthy appearance, her kidneys may be assumed to be healthy, unless there be direct evidence to the contrary; and I always give a favourable prognosis. With one exception all my cases of this age—nine in number—have done well.

It has been long known that "Bright's disease" and "albuminuria" are no longer necessarily synonymous, and the above-mentioned cases demonstrate this view. In the cases of albuminuria there was no Bright's disease, and in those of Bright's disease there was no albuminuria. It appears to me that Mr. Tait has laid too much stress on the existence of heart-clot and too little on the kidney disease, which is the true *fons et origo mali*.

I am, Sir, yours obediently,

GEO. GRANVILLE BANTOCK.

Granville-place, Dec. 1st, 1882.

## "A PAINFUL CASE AT MELBOURNE."

To the Editor of THE LANCET.

SIR,—As a Melbourne practitioner I read with pain your article with the above heading, and I think, with the aid of information received by the last mail, I can put a very different complexion on the affair. I am writing, however, without any authority, and trusting simply to the sworn depositions and the statement of the Chief Secretary in the Victorian Parliament.

The implication that the woman Stentt died under an operation for criminal abortion rests entirely on three facts:—1. That before leaving home she told a female friend that she was going to Dr. Barker's to get him to do it,—and she also told her to put her dinner into the oven to keep it hot, as she would quickly return. 2. That she died in the consulting-room. 3. That Dr. Barker rendered himself responsible for the funeral expenses.

1. In regard to the first point it is sufficient to say, as to her mental condition, that she drank freely; her friend and

intimate, Mrs. Moore, swearing that she would often take a bottle of brandy a day.

2. It is true that she died in the consulting-room, but how long was she there? When she entered the waiting-room Dr. Barker was absent, and a Miss Gatenby was there before her. At 12.30 P.M. Dr. Barker returned and saw Miss Gatenby first, and she left (fortunately there was a clock in the room) at seventeen minutes to one. Between fifteen and ten minutes to one a Mr. Cherry came in, and saw, as he swears, the door open between the two rooms. He had not been there more than two minutes before Dr. Barker, jun., came in the waiting-room for the ammonia-bottle, and remarked to Mr. Cherry that a lady had fainted. So that seven minutes had sufficed for all arrangements, and for carrying them on so far as to cause death, and this, with the door wide open into the waiting-room for any impatient or stupid patient to walk in and see the whole affair! Dr. Barker's account is that on her entry she began to hint at what she wanted, that he put the proposal aside rather sharply, and she then complained of sensations in her abdomen, and slid off the chair on to the floor, fainting, as he thought, but dead as it proved. He then called his son, who was by chance in the house, to aid him, and it was at this period that Dr. Barker, jun., was seen by Mr. Cherry.

But as to the real cause of death. Of this absolute proof is wanting, but her friend, Mrs. Moore, who lived with her in the early part of the year, swears that she used to "go off into fits," and this condition was not likely to be improved by heavy drinking and adultery, with an additional strain from her husband's being constantly expected home from his work up the country. In the post-mortem mention is made of a rupture of the vaginal mucous membrane, up which a probe could pass "for an eighth of an inch." It seems to me very probable that the rupture was post mortem, especially as the examination was made six or seven weeks after death.

It would seem strange that so much could have been made of so little; but certainly Dr. Barker acted rather imprudently. If the body had been simply handed over to the police all this trouble would have been avoided; but he was too sensitive, and suffered for it. In fact, as the Premier said, if the facts now known had appeared at the inquest, public opinion on this subject would have been very different. The Chief Secretary has withdrawn his letter calling on Dr. Barker to resign, and he holds still his high professional offices.—I am, Sir, your obedient servant,

London, Nov. 27th, 1882.

AN AUSTRALIAN F.R.C.S.

\* \* We gladly insert the above letter. Our correspondent does not materially differ from us, except in thinking that Dr. Barker acted "rather" imprudently. We still think that he acted very imprudently, and that the coroner was equally at fault in the matter of prudence. We congratulate Dr. Barker on the fact that his character and the additional facts brought to light by the Government, and mentioned by the Premier, and alluded to in the above letter, have induced the Government to withdraw their request for Dr. Barker's resignation—action on the part of the Government of which we entirely approve.—ED. L.

## THE VACCINATION PROSECUTIONS AT BRIGHTON.

To the Editor of THE LANCET.

SIR,—In your journal of last week there is an annotation on vaccination prosecutions at Brighton, in which reference is made to an article in an evening paper, charging one of the public vaccinators of Brighton with having made the extraordinary statement "that he had no pure vaccine lymph, and if he had he would not use it," and that in consequence, Henry Holman and others, who had brought their children to the public vaccination station, had taken them away unvaccinated. I am the public vaccinator alluded to, and shall feel much obliged if you will kindly allow me to state, most emphatically, that there is no truth whatever in the accusation. I was asked if the vaccine I was using was direct from the calf or cow, and if I could produce the calf for inspection. I replied in the negative, but promised to obtain lymph direct from the calf in a few days if it were

really preferred. This, however, did not satisfy the objectors.

I believe most people would consider that the charge against me refutes itself; it is most certainly of the same reckless character as others which have been from time to time made by the anti-vaccinationists of Brighton, and which hitherto I have thought it quite unnecessary to notice.

I am, Sir, yours faithfully,

LEWIS C. BADCOCK,

Public Vaccinator of the Western District of Brighton.  
Brighton, Dec. 5th, 1882.

\* \* We think it ought to be clearly understood that public vaccinators will be acting wisely in declining to use stored calf lymph if frequent demand is made for it. If animal lymph is to be used for any other purpose than the renewal of stock, it is absolutely necessary that the vaccination should be done directly from the calf.—ED. L.

#### NOTE ON THE DURABILITY OF KOCH'S BACILLI OF TUBERCULOSIS.

To the Editor of THE LANCET.

SIR,—In October last a specimen of phthisical sputum, containing swarms of Koch's bacilli, was kept for thirty-six hours at a temperature above 100° F. At the end of that time it had the characteristic odour of decomposing albuminous substances, and showed under the microscope great numbers of putrefactive organisms; the bacilli of tuberculosis, recognised by their staining reaction, were found quite unchanged. The same specimen was then spread out in a watch-glass, covered to exclude dust, and left to dry partially at the ordinary temperature of the room, usually between 50° and 60° F. This was on October 28th. On December 2nd, a portion was moistened with distilled water, and stained by Gibbs' method; the bacilli were readily found, and showed no appreciable alteration. Desiccation is known to be an excellent method for the preservation of different bacteria, but in this experiment there was no desiccation; the sputum was still moist at the end of the five weeks. The result shows that these organisms are capable of resisting putrefactive changes for a very long time, so far, at least, as their form and staining reaction are concerned; whether under these circumstances they retain the power of growth and reproduction is a different question. I made an attempt to cultivate bacilli from this specimen by Koch's method, but failed; the apparatus used was, however, imperfect.

I am, Sir, yours obediently,

H. S. GABBETT, M.D.,

Assistant Physician and Pathologist to the Royal Chest Hospital.  
December, 1882.

#### "UNQUALIFIED ASSISTANTS."

To the Editor of THE LANCET.

SIR,—As the above-mentioned subject has been under notice in your columns frequently of late, I am anxious through your valuable journal to gather some information on the subject. First, is it right that an unqualified assistant should perform the duties connected with parochial work or other Government appointments? Second, is a medical man justified in leaving such appointments and his practice generally, each probably for a few days, in the hands of such a substitute? Third, as far as I know, it is against certain laws affecting the medical profession that an unqualified man (one who does not even possess an apothecary's certificate) should compound and dispense drugs in an open surgery; is not this the case? Fourth, and lastly, ought medical men to sign death certificates of patients attended by their unqualified assistants, but who during their illness they have not seen personally? If the condition of matters specified by these questions exists, is it not high time attention was directed to this subject?

In these days of "medical reform," when the present system of examinations and qualifications for practice is under review, is it not essential to such a reformation that all "unqualified practice" should henceforth cease, even in the case of "assistants"? It is neither just to the public nor to the younger members of the profession that such men should be permitted to practise medicine, some of whom are

dubbed "doctor," and assume the position of legally qualified practitioners. The fact that a man is not duly qualified should be enough to exclude him from practice. Non-qualification is generally the result of repeated and fruitless efforts to qualify. A man, therefore, who cannot come up to the minimum standard of knowledge necessary to obtain a diploma to practise his art is surely a person who ought not to be trusted with the responsibilities and dangers of actual practice.

I am, Sir, yours faithfully,

December, 1882.

M.B., C.M., &c.

#### THE RECENT EPIDEMIC AT BANGOR.

At a meeting of the medical practitioners of Bangor, held on Tuesday, November 28th, it was resolved that the following letter be forwarded to the press for publication.

Bangor, North Wales, Nov. 28th, 1882.

SIR,—We, the undersigned medical practitioners of Bangor, have much pleasure in stating that the epidemic of typhoid, which has prevailed in this city for some time past, has now subsided, and that the town and neighbourhood are in a remarkably healthy state.

As reports relating to this epidemic have from time to time appeared in your columns, we trust that you will kindly insert this letter.

HUGH B. HUGHES, Surg. C. & A. Infirmary.  
H. R. GREIG HUGHES, Surg. C. & A. Infirmary.  
R. ROWLAND JONES.  
R. LANGFORD JONES, M.R.C.S.  
E. OWEN PRICE, Dep. Med. Officer of Health.  
J. RICHARDS, Phys. C. & A. Infirmary.

RICHARD JONES.  
EDWARD J. LLOYD, M.D.  
H. GREY EDWARDS, M.B., B.Ch.

#### EDINBURGH.

(From our own Correspondent.)

THE weather here for some time past has been extremely inclement, and several of the University professors have been unable to meet their classes. Professor Grainger Stewart, who has been confined to his room for the past fortnight, is, we are glad to hear, now convalescent; Professor Simpson, who was also confined to the house for some days, is also better; and it is hoped that Professor Greenfield, who has also been unwell, will soon be able to resume his duties.

The total number of students who have matriculated at the University this session is, I understand, 2909, being an increase of 94 on the winter session of 1881-82. The increase is mainly due to the medical faculty, in which there is an increase of 76. The increase in first year's medical students is 59; and the total number of medical students attending the University classes is 1388.

Since I last wrote there has also been a considerable improvement in many of the extra-academical classes. The dissecting-rooms at Minto House are quite full. Dr. John Duncan and Dr. Affleck have large classes, while the numbers attending those of the extra-academical lecturers have also increased.

The Health Committee of the Town Council have decided, after mature consideration, to retain the whole of the old surgical hospital as an infectious hospital. It is intended to admit those classes of cases which are not received into the fever hospital belonging to the Royal Infirmary. In the plans provision is made for securing entire isolation of small-pox patients, for affording accommodation for the better class of citizens who may desire, for payment, isolation and treatment in a well-conducted hospital; for observation wards, in which patients, the exact nature of whose cases has not been determined, will be placed; and, lastly, for quarantine or reception wards, which will be used for families of infected houses until the houses in which they reside are properly disinfected. The latter wards are intended to be used in such a case as an epidemic breaking out in a tenement, when, if necessary, the whole of the inhabitants might be removed to the quarantine wards and

there, if thought desirable, for several days, till the  
es are thoroughly disinfected.  
nburgh, Dec. 6th, 1882.

**GLASGOW.**

*(From our own Correspondent.)*

THE Glasgow Police Bill, of the sanitary clauses of which  
THE LANCET published a summary a few weeks ago, has  
been withdrawn. It will not be presented to Par-  
liament during this session at least, on account of the  
motion announced by the Lord Advocate to prepare a  
Police Bill applicable to all the large Scotch towns gene-  
rally. We are in the meantime, therefore, saved from the  
action of what nearly all the medical men of this city  
to be an injustice—namely, the enforcement of the  
notification of infectious diseases by the medical attendant,  
well as by the householder. This principle of "dual  
responsibility" was specially objected to, and strongly  
voiced here. The deputations which waited on the Town  
Council, however, found that body quite enamoured of  
the powers these compulsory notification clauses conferred  
their officers; and it is not at all improbable that had  
the Lord Advocate not upset the Council's calculation we  
could ere long have been saddled with dual responsibility,  
der penalties both severe and cumulative. Not only the  
profession, but the public at large, are pleased that this  
tempt at what has been frequently and well described as  
grandmotherly legislation has fallen through.

The committee in charge of the Southern Hospital scheme  
will soon be able to appeal to the public for funds, with  
finite proposals as to size and style of buildings, &c., on  
which to base their appeal. No fewer than forty-five sets  
of architects' plans have been lodged with the secretary, and  
these are very varied, some time must elapse before a final  
decision is come to regarding them.

Dr. Francis Henderson, whose health compels him to  
move from Helensburgh, and who has for eighteen years  
acted in Helensburgh and the Gareloch district, was, on  
last Saturday afternoon, presented with a drawing-room  
niece and ornaments, £500, and a diamond ring for  
Mrs. Henderson, on the occasion of his removal to Glasgow.  
These gifts were subscribed by 102 patients and friends, in  
grateful acknowledgment of professional skill and in token  
of esteem and affection on the part of the community.

The "annual meeting" season is once more upon us.  
Apparently the influence of Christmas is supposed to have a  
stimulating effect in the liberality of subscribers. That most  
reserving institution the Glasgow Maternity Hospital held  
its annual meeting a few days ago. The report showed that  
56 cases had been treated in hospital, and 1254 at home;  
total 1510, or an increase of 260 over last year. No fewer  
than 154 students attended at the hospital and benefited by  
its practice last year.

**SCOTTISH NOTES.**

*(From our own Correspondent.)*

THE sanitary condition of the Aberdeen Royal Infirmary  
has frequently been the subject of adverse criticism by  
members of the directorate and others, while the remedies  
to be applied were not so obvious. It has been recognised  
by well-wishers of the institution that when drainage and  
closet arrangements came to be overhauled changes of a  
more considerable kind would also be necessary; and the  
recent discussions as to a proposed new wing, &c., make  
the present a suitable opportunity for giving anxious thought  
to the very complete scheme now propounded by Dr. Angus  
Fraser. Should this or any similar plan be followed, the  
extensions and improvements will be alike great. At  
present there is deficient accommodation for patients, a want  
of special wards, insufficient provision for the resident staff,  
nurses, and servants, and defective watercloset and bath  
accommodation. Dr. Fraser proposes that four pavilions of  
three floors each, wholly devoted to the reception of patients,  
should be formed by extending the present wings; that  
each of these twelve wards should measure sixty feet by  
twenty-three feet; that the central part of the present  
building should be reserved as the administrative part of the

institution, and provision made, on a line with the central  
block, for the various special wards. By these means the  
number of beds available would be largely increased, and  
clinical teaching much facilitated. Now that the matter  
is ripe for discussion and action, it is to be hoped that the  
directors will institute structural changes on a sufficient  
scale; and the profession will be further interested in  
knowing how the proposals for the increase of the staff, as  
well as that most needful of reforms, the provision of better  
means for gynecological teaching, shall be met.

Typhus fever has again made its appearance in Aberdeen,  
and apparently in a virulent form. The medical officer of  
health has taken vigorous action, which it is hoped may be  
successful; but, looking to the less immediate future, there  
is, perhaps, more hope in the proposed inquiry as to the  
desirability of dealing with certain parts of the city under  
the Artisans' Dwellings Improvement Act. Dr. Beveridge  
may be trusted for energetic action as chairman of the Health  
Committee, and if he determine that the Act should be  
put in force, it is just possible that the hard-headed citizens  
may agree with him that it is better to begin the improve-  
ment of the town by efforts at eradicating such preventable  
diseases as now so frequently make their appearance. In  
the meantime the Council has determined to proceed with the  
City Improvements Bill. It would seem that the Board of  
Supervision can occasionally be peremptory enough in their  
demands upon local authorities, and the Inverkeithing Town  
Council has this week come under the lash. The inspecting  
officer of the Board has had grave reason to complain of the  
neglect of drainage in their small town, and a demand is  
now made that within fourteen days a report on its sanitary  
condition be transmitted. The Council, at their meeting  
a few days ago, determined to place the matter in the hands  
of an engineer, with a view to the immediate carrying out  
of a proper drainage system.

The Dundee authorities have now received Dr. Stevenson  
Macadam's analysis and report upon the Monikie water,  
the admission of which to the town is causing some interest.  
The question in dispute is whether the water should be  
filtered or unfiltered, as preparation for this process will cost  
£15,000; and samples of both qualities were sent for  
analysis. Dr. Macadam shows that the amount of organic  
and volatile matter is less in the filtered water, but that  
such matter in either or both waters is of a harmless and  
innocuous character. Some of the Commissioners, in view  
of the latter statement, object to the proposed outlay, and  
further discussion of the subject has been delayed.

Previous to last session, graduates of Scotch universities  
had it in their option whether to become members of the  
general council; but an Act was then passed which made  
this one of the conditions of graduation. Formerly either  
political party was willing to pay the necessary fee and so  
to secure the future vote; but it appears that there were  
many men who refused even this easy method and declined  
to register. This is brought out by the now published  
returns referring to Edinburgh and St. Andrews, as more  
than double the usual number is this year added to the  
parliamentary roll. Of the 353 members, Edinburgh claims  
318, and St. Andrews 35.

An epidemic of typhoid fever, causing the local authorities  
much anxiety, has occurred in the neighbouring towns of  
Dumfries and Maxwelltown. It appears that cases were,  
so far as space allowed, admitted to the Dumfries Infirmary,  
but that the accommodation there was of the most meagre  
kind. There is no special hospital for infectious diseases in  
the place; and Professor MacLagan, of Edinburgh, has been  
invited to advise the authorities in the circumstances.  
Though a good deal has been done in Scotland since the  
passing of the Public Health Act towards providing adequate  
hospital accommodation, much remains to be effected; and  
it seems only in response to local scares, such as is now  
affecting Dumfries, that any advance is made.

**IRELAND.**

*(From our own Correspondent.)*

THE first meeting of the Academy of Medicine took place  
last week, when the Pathological Section was inaugurated  
by an address from Dr. J. M'Purser. There was a large  
attendance of members present.

Complaints have recently been made by the guardians of

the South Dublin Union, to the effect that the medical staff belonging to the workhouse do not attend as regularly as they should; and that upon numerous occasions lately, when their services were required for urgent cases arising at night, they were not available when sent for. It was also suggested that resident medical officers should be appointed in place of the visiting staff. Drs. Jennings, Burne, and Owens, in addressing the Board on this subject, stated that it would inevitably tend to the disadvantage of the sick poor if the staff were now to be reduced, when the number of sick and infirm have so largely increased. The staff have the advantage of immediate consultation with each other in complicated or difficult cases, so that the inmates of the workhouse are, as regards skill and attention, placed on a level with the wealthy classes of society. As regards the charge of inattention, they remarked that the statement is as unworthy of notice as incapable of proof. The consideration of the matter has been deferred for a few days.

The new scheme which has been adopted for providing special departments in the Belfast Royal Hospital has not met with general satisfaction, and it is thought by a good number that the hospital does not possess the requisite space nor the necessary funds for carrying out these additions to the institution. It has been stated that the greatest difficulty has been experienced in finding room for the majority of patients seeking admission, and that recently when application was made by one of the staff for a ward to isolate certain cases it could not be obtained from want of room. It has been estimated that the twelve beds for diseases of the eye and ear, and diseases of women, will not cost more than £40 a year; but a more probable estimate may be fixed at fully ten times that amount, more especially if the cost of the extern departments is included in this sum. For a populous town like Belfast, rapidly increasing in wealth and the number of its inhabitants, it appears strange that but one general hospital should be considered sufficient, and it seems desirable that another institution similar to the Belfast Royal Hospital should be established, which would permit additional space in both hospitals for special departments.

Mr. Rawdon Macnamara, of the Meath Hospital, has had a very serious attack of erysipelas, but I am happy to state that he is now progressing favourably.

Dr. A. Spencer, whose death from typhus fever took place some time ago, has left his widow in bad circumstances, and a subscription has been started on her behalf.

A well-trained nurse, to carry out efficiently the orders of the medical attendant, occupies a very important position in the treatment of the sick. Consequently the Belfast Nurses' Home and Training School may be regarded as a valuable institution, for during the past ten years it has sent out eighty-six nurses, trained in the Home, for hospital and private nursing; it has also supplied matrons to several infirmaries in Ireland, and nurses to various parts of the colonies. It is satisfactory to learn that the institution is prospering, and that it is now entirely free from debt.

Mr. J. G. Chidley, A.B., late resident pupil of the Hardwicke Fever Hospital, recently died from an attack of typhus fever, which he contracted in the discharge of his duty. The esteem in which the deceased young gentleman was held was shown at his funeral, when a large number of his friends and comrades assembled to pay the last tribute of respect to his memory. The remains, on reaching the churchyard, were borne by the students to the grave, and on the coffin were placed some handsome wreaths presented by those present.

In an annotation at p. 956 of last week's LANCET, on the recent outrages in Dublin, by a printer's error it was made to appear that the gentleman who had been stabbed by assassins near his residence had died. This was not the case; but his condition at the time was critical. It is satisfactory to state that he is now progressing fairly towards recovery. Dooley, or Dowling, the man who shot Cox, has improved so much since his admission into the hospital, that it is expected he will be able this week to be transferred to Kilmainham prison.

During the past month nearly 200 deaths from diseases of the lungs took place in Belfast, principally owing to variations of temperature and the excessive amount of moisture present in the atmosphere. Scarlatina prevailed to a considerable extent, some of the cases being of a very malignant character.

## PARIS.

(From our Paris Correspondent.)

THE horrible event which took place in Paris about the middle of October, when, as will be recollected, a young lady, aged about twenty, committed suicide by throwing herself off one of the towers of Notre Dame, her body being found on the railings of the cathedral literally severed in two across the lower part of the trunk, has led to a very interesting discussion from a scientific point of view. The question was raised as to the manner in which death took place in this case. Professor Brouardel, the medical jurist of Paris, stated in his report, that owing to the rapidity of the fall, death was caused by asphyxia, and not by the section of the body. He founded his argument on the fact that the velocity of a body falling from a height passes through five metres of space in the first second, fifteen metres in the second, twenty-five metres in the third, and thirty-five in the fourth second; consequently, the fall of the body in this case would occupy four seconds, the distance traversed being eighty metres, which is the height of the tower; but as the unfortunate victim fell on the balustrade, which is ten metres above the ground, this would make the duration of the fall rather less than four seconds. M. G. Bontemps, of Amboise, writing in *Nature*, the homonym of the English publication, endeavours to refute M. Brouardel's conclusions by observing that the velocity above mentioned is less than that of the rapidity of the mail train to India, which he considers to be even less than the physiological limit of speed a man could go through with impunity, as is verified every day by the engine-drivers and stokers of these trains. In response to this, another writer remarks that the argument of the correspondent in *Nature* is equally erroneous, as the engines of all rapid trains are in all seasons, and some of the other trains in winter, provided with a screen, in which are fitted with two discs of glass, which shelters the engine-driver against the enormous pressure of the air, without which arrangement the driver would not be able to support it for two minutes, particularly when to the rapidity of the course is added a cold wind blowing towards the train at the rate of ten metres per second. The latter author concludes that the young lady in question could not have been completely asphyxiated when her body reached the balustrade, but she must have been insensible, and thus relieved of the consciousness of the horrible mutilation her body was subjected to.

The application of the actual cautery to the neck of the womb in certain affections of that organ may be a useful means of treatment in able hands, but when employed indiscriminately the temporary benefit which a few patients may derive from it will not counterbalance the dangers attending it; for in many cases the mischief inflicted by the use of the red-hot iron has been so great, almost irreparable, that many gynecologists have rejected it altogether in their practice. Certain practitioners employ the actual cautery in uterine affections under the conviction that it is perfectly harmless, and that nothing but advantage could be derived from it. To these may be applied the well-known adage of Morgagni: "Sunt plures medici qui agros ob id interimunt quia nesciunt ipsi quiescere." Dr. Sireday, Physician to the Lariboisiere Hospital, has given the following illustration, to show that such a practice is not devoid of danger. A patient who had been treated at her home for metritis, and to whom the actual cautery had been applied for some months, entered M. Sireday's ward for severe dysmenorrhoea with almost complete retention of the menses. On examination Dr. Sireday discovered that owing to the influence of the repeated application of the red-hot iron the neck of the womb was all but completely destroyed; its orifice was so narrow that it was impossible to introduce into it an ordinary pocket-case probe. After prolonged treatment by gradual dilatation of the canal, the latter was rendered permeable, but the cure was not complete; the patient was obliged to return to the hospital as all her sufferings recurred, and she went through the same treatment for some time. Dr. Sireday remarks that this is only one among many such cases that have come under his observation, and he could cite others where the application of the actual cautery to the neck of the womb was attended with fatal results owing to consecutive metro-peritonitis.

An unsuspected source of public poisoning has been brought

notice of the police authorities, arising from the use of kerosene and confectioners, for the purpose of heating ovens, of old beams, &c., procured from the demolition of houses. This timber is generally painted with preparations of lead, copper, and arsenic, and it is often found that the ashes left after combustion contain or less of these poisonous substances, which adhere to the sides of the ovens and to the bread and confectionery and after baking. The timber employed for telegraph poles, railway sleepers, &c., present the same dangers, as it is generally painted over, or impregnated, with different mineral solutions, such as the sulphate of copper, arsenic sublimated, &c., for the purpose of preserving the timber. The Prefect of Police has, therefore, forbidden the use of the timber obtained from the above sources by bakers and confectioners.

Those coming over to the continent will be repaid by a visit to the aquarium at Havre, which has just been opened by an interesting fish rarely met with in these latitudes. This fish, which was caught by the crew of a pilot boat, is known under the name of moon-fish, from its resemblance to the earth's satellite, and belongs to the family of "gymnodontes." The body of the fish is raised and arched, the skin shines like highly-polished silver, and it is said that when the fish floats on the surface of the water its body is quite phosphorescent. It measures one metre in length by one metre forty centimetres from the superior fin to the dorsal fins to those of the anal extremity.

In my last communication, on M. Gambetta's wound, I gave a 954, for "Ville d'Arzay," read *Ville d'Avray*.] Paris, December 5th, 1882.

---

THE UNITED STATES NATIONAL BOARD OF HEALTH AND VACCINATION OF IMMIGRANTS.

(From a Correspondent.)

ONE of the most useful branches of service of the National Board of Health (United States) is a system of inspection and vaccination of immigrants. Four years ago there was a death by small-pox reported in the United States. Since then began a remarkable increase of immigration from the continent of Europe, and especially of Polish and Russian Jews, who are generally unvaccinated. As they generally remained in the foreign seaport towns several days before embarking, and usually occupied low lodging-houses where contagious diseases were prevalent, small-pox began to appear among them. As ocean transit now occupies but ten days, an infected emigrant could reach our ports in apparent health, and pass quarantine unsuspected. More than that, he can take cars on arrival, and reach a distant western settlement within the period of incubation. It very naturally appeared that with this rising tide of immigration small-pox outbreaks began to be more and more frequent in the Western States, until at length the pestilence was regarded as epidemic. To meet the emergency the National Board of Health organised a system of inspection and vaccination of immigrants, which has now been in operation about five months, and has given the most satisfactory results. The work begins with the embarkation of the emigrant in the foreign port, and he is followed to his destination in his western home. The shipsurgeon is required to examine every emigrant with reference to the evidences of protection by vaccination. If they are not present, or are unsatisfactory, the surgeon proceeds to vaccinate. To all protected persons he issues a card bearing the following information, as an example, printed upon it:—

CUNARD LINE.

VACCINATED.

S.S. SCYTHIA.

(Signed)

W. J. KING, Surgeon.

when required. It is first presented to the port physician, and then to the sanitary inspectors on the railroads, at the various inspection stations. The railroad inspections are comparatively easy, for the immigrant trains are made up like freight trains, and run at regular intervals, conveying only immigrants. Usually the inspectors board the train at some convenient station, and carry on the inspection and vaccination while the trains are moving, thus causing no delay. I have before me the monthly statement of the Supervising Inspector of one district—viz., the Western district. It shows a total of 14,924 inspections, and 2918 vaccinations; 234 had never been vaccinated. During the four months ending September 30th the total number of inspections in that district was 78,366, and of vaccinations 13,842. The result of this service, the first of the kind ever established, I believe, has been most useful. Not only have small-pox outbreaks ceased, but the inspectors have intercepted other contagious diseases, as scarlet fever, measles, and diphtheria. They have also greatly improved the sanitary condition of the immigrant trains. Inspector Ranch remarks:—"Evidence of the growing interest in this protective measure is found in the increasing numbers of immigrants vaccinated or revaccinated just before sailing. This is especially true of the English and Scotch, and in a great measure offsets the occasional opposition to the inspection met with from individuals of the same nationalities, and which seems to be due to the anti-vaccinationists of Great Britain."

New York, October 15th, 1882.

---

TENEMENT HOUSES IN AMERICA.

(From a Roving Correspondent.)

It is popularly supposed that in the large towns of America there are no poor, in the English meaning of that term. This is, however, a great mistake, and as a matter of fact some American cities contain as degraded specimens of the class of people to be found in tenement houses in Great Britain as will be met with anywhere in the world. It may be interesting to inquire how it is that in the New World, where labour is at a premium, and where there is more work to be done than hands to do it, no improvement has taken place in that class of persons who inhabit tenement houses. In a town like Chicago, which has been nearly rebuilt during the last ten years, the cause of the existence of the worst class of tenement house is due to the fact that the enormous number of emigrants who annually enter the capital of the West far exceeds the capacity of builders and capitalists. Hundreds of new houses are erected annually, but an influx of 60,000 or 80,000 emigrants renders it impossible to provide suitable house-room for all. In spite of many difficulties, however, it must be confessed that the health authorities, under the energetic superintendence of Dr. De Wolf, the able Commissioner of Health, have done great public service. Mainly at their instigation, and in spite of considerable opposition from various quarters, powers have been conferred upon the health authorities which, as they are vigorously exercised, have proved the greatest boon to the inhabitants of Chicago. The following are the chief sections of an Act for the regulation and inspection of tenements and lodging-houses and other places of habitation, which was approved and put in force on and from May 30th, 1881. The Act applies to all incorporated cities of 50,000 inhabitants within the State of Illinois.

1. Architects, builders, or other persons interested in any projected tenement, lodging-house, or other place of habitation, must submit plans and specifications of any such building to the Health Commissioners, to enable them to examine, approve, or reject the same unless or until adequate provision is made for the ventilation of rooms, light, and air-shafts, windows, ventilation of waterclosets, drainage, and plumbing.
2. Every plumber interested in the plumbing work of such buildings must receive from, and proceed according to the specifications and written instructions of, the Health Commissioners before commencing work.
3. The plumber is compelled, after the completion of his work, and before any portion of it is covered up, to notify the Commissioners in writing that the buildings are ready for inspection, and it is unlawful for any person interested to cover up or in any way conceal such plumbing work in or

about any such buildings until the Health Commissioners have approved it.

4. Provision is made to impose a penalty for every such offence of from £20 to £40 upon any architect or builder who fails to comply with the foregoing regulations.

5. A similar penalty is imposed upon plumbers in case they fail to comply with the law, together with a further penalty of "£2 for each and every day such plumbers shall after first conviction neglect or refuse to obey the Act or the written instructions of the Health Commissioners," with a forfeiture of his licence to do business in the said city for one year after conviction for a second offence.

With the view of facilitating the application of the above Act various printed forms have been prepared by the Health Department, which provide (a) plans for ventilation, light, plumbing, and drainage; (b) permit signed by Health Commissioner sanctioning the erection of buildings on the following or some special conditions in certain cases.

(1) Every habitable room must have at least one window opening directly upon the street or yard, or upon a court or light shaft. (2) Every light and air shaft for habitable rooms must be at least twelve square feet in area for a three storey house, sixteen square feet for a four storey house, and twenty square feet in area for a five storey house; and in every case not less than two feet wide in the clear. Shafts between two houses and common to both must be double this area. (3) All windows which open on shafts shall be hung with weights so as to slide vertically, each window being not less than twelve square feet in area. (4) Water-closets shall not be ventilated by a shaft which ventilates habitable rooms where they do not open otherwise to the external air. Waterclosets must be ventilated by means of a separate shaft, not less than three square feet in area, to extend above the roof, and to be arranged for the admission of light and air at the top. (5) No alteration in the light and ventilation of the premises (for which a permit is granted) shall be made except upon the express written approval of the Commissioner of Health; nor shall any additional structure be erected upon the lot without such approval, and a special permit. Printed upon the face of the permit are details of the plan of plumbing, which will be insisted upon by the Commissioner of Health. This plan provides that all materials used must be of good quality and free from defects, and all work must be executed in a thorough and proper manner. All plumbing must be so placed as to be readily inspected. Every soil- and waste-pipe, iron or lead, must extend through and at least four feet above the roof, be of undiminished size, and provided with suitable top or cap. The house-drain, if of iron—a material much used for these pipes in America—shall have a fall of at least half an inch to the foot, and be provided with a proper trap near the street, and with an inlet for fresh air inside the trap. It should run along the cellar walls—a favourite plan in America—and never be hidden underground. All iron soil-pipes must be sound, free from holes, of a uniform thickness, of not less than  $\frac{1}{4}$  in. for a diameter of two, three, or four inches, or  $\frac{3}{8}$  in. for a diameter of five or six inches. Before connexion they must be thoroughly coated with coal tar pitch, inside and outside, which must be applied hot. All joints in the soil- and waste-pipes must be so caulked with lead, or cement made of iron filings and sal ammoniac, as to make them impermeable to gases. When the house-drains are not of iron they must have twice the above given internal diameter and half the grade, unless in special cases specially sanctioned. Every sink, drain, water-closet, and tub, or set of tubs, must be separately and properly trapped. When a lead pipe or trap is connected with an iron pipe the joint must be made through a metallic sleeve or ferrule, and be caulked with lead. All traps must be ventilated by a special pipe entering above the roof. Every "safe" under a basin, bath, or other fixture, must be drained by a special pipe, not directly connected with any waste-pipe, drain, or sewer. Every water-closet must be supplied with water from a special cistern, and not direct from the main. No overflow-pipe from the cistern to be directly communicated with any soil- or waste-pipe or drain. No cistern for drinking water to be lined with lead. It is stated that wrought iron, steam-fitted, glazed pipes are the best for house drains, and their use is recommended. When the work is completed, and before it is covered up and the house occupied, the Health Department must be notified, to enable the authorities to send an inspector, upon whose report the Commissioner will act before its final approval. Equally stringent regulations are enforced in respect to the

existing or old tenement houses, which are regularly inspected by a staff of trained officials, and it may be said with truth of Chicago that there, if anywhere in the world, the life of a jerry builder, or plumber, or owner is not a happy one. For this reason, and as a guide to those who are striving for improvement in these matters in England, the above regulations and information cannot fail to be of interest. The whole plan of administering the Health Department of Chicago has been admirably conceived, and is being ably administered by Dr. De Woolf, the present Commissioner of Health. I would advise anyone who desires to have a model set of forms and regulations for controlling the health arrangements of a large town, to write to Dr. De Woolf for those in use at Chicago. It is not a little surprising to find that whereas wages are exceedingly high throughout America, salaries, and especially the remuneration of the health officers, are unusually small and inadequate.

(To be concluded.)

## Obituary.

EDWARDS CRISP, M.D.

WITH the death of the subject of this memoir a striking if not an imposing figure disappears from the stage of medicine. A man of indomitable courage, self-reliance, and energy, of unimpeachable integrity and utter unselfishness, of unwearied industry, of high attainments, and (at any rate as far as his profession was concerned) of much practical sagacity, Dr. Crisp ought to have attained a much higher eminence among the medical men of his time than he actually did attain, or than an impartial posterity will accord him. He commenced his professional career as a general practitioner, and rapidly rose into large and lucrative practice; and there is no doubt that, had he remained in general practice, he would have been one of the foremost general practitioners of his time. Had he been fortunate enough in early life to have been appointed physician or surgeon to a London hospital we have every reason to believe that he would have achieved high eminence as a consulting practitioner and teacher. Or had his early scientific training been more exact and more complete than it was, and had he consecrated his life from the first to scientific pursuits, he would probably have made a distinguished name for himself as an anatomist, a physiologist, or a pathologist. But, unfortunately for him, he seceded from general practice at the time when success in it was assured; and he entered upon consulting practice and the pursuit of scientific medicine under unfavourable conditions, which warped his judgment and led him to waste many of his best years in controversy and warfare. But with all his failings Dr. Crisp was a man who commands our sympathy and respect, and especially was one whom general practitioners may feel proud to regard as one of themselves; for he ended his life as he commenced it—in general practice; and the works by which he will be best remembered are those which he gave to the world while he was a general practitioner. We refer to his important observations on the relation between Chlorosis and Ulcer of the Stomach in young women, and his Jacksonian Prize Essay on the Structure, Diseases, and Injuries of the Bloodvessels.

Dr. Crisp was the son of Mr. Edwards Crisp, a gentleman farmer, and of Mary his wife. He was born at Rendlesham, Suffolk, on Dec. 10th, 1806, and was educated at the Grammar School at Ipswich. In 1823 he was apprenticed to Dr. Cream of Long Melford, and in 1826 entered as a pupil at the combined schools of St. Thomas and Guy's, and pursued his studies there for two years. He became a licentiate of the Apothecaries' Hall in 1828, and a member of the College of Surgeons in 1829. During the years 1829 and 1830 he studied in Paris, mainly at the *Hôtel Dieu* and *La Pitié*, and thus not only acquired a good knowledge of French medicine and surgery, but became an accomplished French scholar.

After the completion of his education he resided for a short time with the late Mr. Bristowe of Camberwell, and in 1830 commenced practice in Brixton. The following year he removed to the Walworth-road, where he conducted a large and increasing general practice for the next fifteen or sixteen years.

It was probably the success of his work on the Arteries

tend during this period), and the credit it brought him, that rmined him to become a physician. He disposed of his tice in Walworth and went over to Dublin to study there; to Scotland, where, in 1848, he obtained the M.D. degree of University of St. Andrews. Then, returning to London, resented himself before the censors of the Royal College Physicians as a candidate for the membership. Un- nately he was rejected; and, still more unfortunately, ead of bearing his disappointment, and offering himself in on a future occasion, he made a violent attack on the miners and published his own version of the examination had undergone. His thorough honesty and truthfulness re manifested in this ill-judged production, for no as- tions of their own could have justified his examiners in eyes of the profession so strongly as they were justified Dr. Crisp's own testimony. We need not pursue this oject further than to say that this incident gave a polemical us to most of his work and writings during the next few ars; and that for some time he conducted, almost unaided, th much vigour and no inconsiderable literary ability, a onthly journal called the *Medical Examiner*, in which he posed, with some virulence, the shortcomings and errors the various examining bodies, but in which, also, strenuously advocated many reforms, of which some ve been already carried out, and others will doubtless llow.

It was about this time that he started practice as a ysician in Parliament-street, where he resided until ie year 1857. He then removed to the King's-parade, helsea, where he remained five years. During the whole f this time he was engaged in consulting practice and in cientific pursuits. He had married, however, about the year 846, and the expenses and responsibilities attendant on n increasing family at length determined him to resume eneral practice. This he did twenty years ago, and emoved to Beaufort-street, Chelsea, where he resided henceforth.

This was probably the happiest period of his life. He ad ceased to be systematically aggressive in medical politics. He conducted a large general practice among patients whom he made his friends. He was a constant attendant at the Pathological and Medical Societies, and took an active share in their proceedings. He spent much of his time in patho- logical investigations, mainly in reference to the lower animals and to parasites. And he found happiness and peace in the society of his wife and in the education of his children; for he was pre-eminently a domestic man, and a loving and unselfish husband and father.

The amount of work which Dr. Crisp accomplished in his life-time was amazing. He published innumerable papers on Medicine, Surgery, Zoology, Physiology, and Pathology in the medical and zoological journals, and in the Trans- actions of the Pathological Society. He obtained the Jacksonian Prize for his work on the "Structure and Diseases of the Large Vessels"; the Astley Cooper Prize for the essay "On the Structure and Use of the Thyroid Gland"; the Astley Cooper Prize, again, for his essay "On the Pancreas"; the Jacksonian Prize a second time for his treatise on "Intestinal Obstructions within the Abdomen"; the Fothergillian Prize for an essay on "Croup and Diph- theria"; and a prize from the Bath and West of England Society for a paper on "Lamb Disease." It may be added that he first demonstrated the existence of valves in the splenic vein.

For some years he habitually dissected the animals dying at the Zoological Gardens; he was always a zealous student of comparative anatomy; and he gradually accumulated (besides a very large collection of parasites) a museum of comparative and pathological anatomy, comprising over 5000 specimens.

Amongst the many honours Dr. Crisp obtained were those of a vice-presidency of the Pathological Society and a coun- cillorship of the Pathological Section of the International Medical Congress when it met in London in 1881.

Dr. Crisp was a short, strongly-built, active man, with a massive bald head, a handsome face, a genial smile, and a pleasant musical voice. He was a ready, self-reliant speaker, always prompt to attack, but ever ready to ac- knowledge his own mistakes. He was a warm friend and (excepting towards the Colleges) a generous enemy. He had much literary and artistic taste.

His health during a long life had been singularly good; and he died without warning, probably of spasm of the heart, on the morning of November 15th.

RICHARD CROSS, M.D., F.R.C.S., J.P.

We regret to record the death on Nov. 19th of Dr. Cross, who for forty-two years had occupied a prominent position as a medical practitioner in Scarborough. He was at the time of his decease Surgeon-Major on the staff of the North and East Riding Brigade of Artillery Volunteers, a Justice of the Peace for the Borough, Fellow of the Royal College of Surgeons, and of the Royal Medico-Chirurgical and Obstetrical Societies. He was Mayor of Scarborough in 186 and occupied the position of alderman for many years. His qualifications were M.D. (1852), M.R.C.S. (1840), L.S.A. (1839). He was held in high honour and esteem not only for his professional qualities, but also for the courtesy and geniality which he manifested to everyone with whom he came in contact. The mayor and corporation, the magis- trates, the artillery, and the rifle volunteers attended his funeral, and the whole route from his house to the cemetery was thronged by thousands of spectators. His son, Mr. T. B. Cross, M.A. of Caius College, Cambridge, succeeds to his practice.

Medical News.

APOTHECARIES' HALL.—The following gentlemen passed the examination in the Science and Practice of Medi- cine, and received certificates to practise, on Nov. 30th:—

- Holton, Richard, Lincoln.
- Masters, Alfred Thomas, Westbury-road, Westbourne-square.
- Osborn, Frank Charles, Keppel-street.
- South, George, Peckham.

The following gentlemen also on the same day passed the Primary Professional Examination:—

- Albert Bowhay, Walter Horncastle Burrows, and Charles Langford Josling, Charing-cross Hospital; Walter Wise, Middlesex Hospital.

THE Stoke-upon-Trent Board of Guardians have decided to expend £13,000 on the erection of a new hospital at the workhouse.

ROYAL INSTITUTION OF GREAT BRITAIN.—Acheson George Bartley, M.D., M.A., David Edward Hughes, Esq., F.R.S., and George Law, Esq., F.R.G.S., F.Z.S., have been elected members of the Institution.

THE EASTBOURNE NEW MEMORIAL HOSPITAL will, it is expected, be opened by the Prince of Wales in the spring. The collections and proceeds of a concert amount to £2280, but much more is required to enable the institution to start free from debt.

VACCINATION GRANTS.—The following gentlemen have received the Government grant for efficient vaccina- tion in their respective districts:—Mr. William Dobson, Holbeck Union, Leeds; Mr. J. Hamilton, Gresley district, Burton-on-Trent Union (third time); Mr. Roberts, Barnolds- wick (third time).

REMARKABLE FECUNDITY.—A woman aged fifty- seven, living at Aberdare, is stated to have borne no fewer than thirty-two children. The prolific mother had had twins on three occasions, triplets twice, and once four at a birth. The father was in receipt of parish relief, which, perhaps, is hardly surprising.

At a meeting last week in the parlour of the Mayor of Manchester resolutions were carried to the effect that it is desirable that a museum be erected in connexion with Owens College, and that a fund of not less than £50,000 be raised for the purpose. The buildings are to be constructed from a design by Mr. Alfred Waterhouse, under instructions from the Court of Governors of the College. Promises of sums to the amount of £20,000 have been re- ceived, and for the remainder of the cost a canvass will be made.

SOCIETY FOR THE RELIEF OF WIDOWS AND ORPHANS OF MEDICAL MEN.—A special general meeting of the Society was held on Friday, November 24th, at 5 P.M., to confirm certain alterations of the by-laws that had been approved at a special general meeting held on November 3rd. The Pre- sident, Sir George Burrows, Bart., took the chair. The chief

alterations made in the by-laws were as follows:—The sum required to qualify as an honorary member was reduced by ten guineas; the proposals for membership and the declarations of widows and orphans may now be signed by two registered medical practitioners, instead of by two members of the Society; the admission fee was abolished; the income of the widow eligible for relief was raised from £50 to £80, and certain powers were given to the directors to make extra grants under special circumstances; the age of the orphans eligible for relief was raised to sixteen years, and in the case of complete orphans to eighteen, and the amount of income of orphans was also increased; in the case of a widow of a member marrying she now ceases under the new by-laws to have any claim on the Society.

**CONSUMPTION HOSPITAL, BROMPTON.**—At a quarterly court of the governors of this charity held at the hospital last week, it was announced that since the last court necessary and extensive repairs to the east wing had been effected, the inmates having been temporarily removed to the new building opposite, in order the more thoroughly to carry out the work. The repairs to the west wing were now in progress, and when completed the patients would re-occupy the vacant wards in the older building. Should the state of the funds admit of it, a further portion of the extension building would then be filled with new patients.

**COLLEGE OF PRECEPTORS' EXAMINATIONS.**—The entries of candidates for the half-yearly examinations of the College of Preceptors, which began on Tuesday last, and were carried on simultaneously in London and at fifty-five local centres in various parts of the country, exceeded 8300, making, with those examined at Midsummer, close upon 13,000 for the year. A supplementary examination, for the preliminary literary subjects required for students of medicine, law, the Royal Veterinary College, the Pharmaceutical Society, and other bodies by whom the certificates of the College are recognised, will be held in March next in London and at four provincial centres—viz., University College, Liverpool; the Leeds Medical School; Queen's College, Birmingham; and University College, Bristol.

**LONDON HOSPITAL MEDICAL CLUB.**—On the evening of Nov. 30th a convivial meeting of the above Club was held at the Holborn Restaurant. Mr. James E. Adams presided, and was supported by a large number of members and their friends. The Club was founded in 1838, but an anniversary meeting of the gentlemen educated at the London Hospital was held as long ago as 1792, and very likely before that time, as the London Hospital Medical School was the first complete Medical School in the metropolis. Special interest attended the present meeting from the fact that the chairman's father, Mr. John Adams, was for twenty-four years the popular secretary to the Club. The toast of the chairman, proposed by Mr. Hutchinson, and of the secretary, given by Dr. Christie, were drunk with more than ordinary cordiality and with all honours. Allusion was made by the secretary to the loss sustained by the Club in the lamented death of Mr. George Critchett, and to the increasing prosperity of the Club, as shown by the constant augmentation in the number of members and of the balance in hand—more than £200.

## Medical Appointments.

*Intimations for this column must be sent DIRECT to the Office of THE LANCET before 9 o'clock on Thursday Morning at the latest.*

**ADAMS, MATHEW ALGERNON, F.R.C.S.Eng., L.S.A.Lond.,** has been reappointed Public Analyst for the County of Kent.  
**BERNARD, GEO. PETERSON, L.R.C.P. Ed., L.F.P.S. Glas.,** has been reappointed Medical Officer and Public Vaccinator for the Flanshead District of the Hemel Hempstead Union.  
**BUTLER-SMYTHE, A. C., M.R.C.S., M.R.C.P. Ed.,** has been appointed Surgeon to the Hospital for Women, Vincent-square, S.W.  
**FINN, EUGENE, M.B., L.K.Q.C.P.I., L.R.C.S. Ed.,** has been appointed Consulting Physician to the North Infirmary, Cork.  
**GETTINGS, J. S., M.R.C.S.,** has been appointed Medical Officer for the Ogley Hay District of the Lichfield Union.  
**GORDON-JONES, W. G., L.D.S.,** has been appointed Honorary Dental Surgeon to the Princess Mary Village Homes.  
**GUEST, ALEX. H., L.R.C.P. Ed., L.F.P.S. Glas.,** has been appointed Medical Officer for the Second District of the Chorlton Union.

**IRELAND, W. WOTHERSPOON, M.D. Ed.,** has been appointed Medical Officer to Miss Mary Murray's Hospital for Girls, near Preston-pans.  
**JACKSON, PAUL, L.S.A.Lond.,** has been appointed Resident Obstetric Assistant at Westminster Hospital, vice C. H. Wise, M.D.  
**JESSETT, FREDERICK B., F.R.C.S. Eng.,** has been appointed Surgeon to the General Dispensary, Bartholomew-close, vice Morrant Baker, resigned.  
**LE QUESNE, EDWIN JOSEPH, L.R.C.P. Lond., M.R.C.S., L.S.A.Lond.,** has been appointed Medical Officer and Public Vaccinator for the Tring District of the Great Berkhamstead Union, vice Lipscombe, resigned.  
**LLOYD, JAS. HELLINGS, L.R.C.P. Ed., M.R.C.S.,** has been appointed Medical Officer for the Callompton District of the Tiverton Union.  
**OSBORN, CHARLES, L.R.C.P. Ed., M.R.C.S., L.S.A.Lond.,** has been reappointed Medical Officer of Health for the Bognor Urban Sanitary District.  
**ROBERTS, ALFRED, M.R.C.S., L.S.A.Lond.,** has been appointed Consulting Surgeon to Prince Alfred Hospital, Sydney, New South Wales.  
**ROUNDTREE, THOMAS W., M.D.,** has been appointed Resident Surgeon and Apothecary to the South Infirmary, Cork, vice Cummins, resigned.  
**SPENCE, WILLIAM JAMES, L.R.C.P. Ed., L.R.C.S. Ed.,** has been appointed House-Surgeon to the Bradford Infirmary, vice Hollis, resigned.  
**STRETTON, Mr. J. LIONEL,** has been appointed Honorary Surgeon to the Kidderminster Infirmary, vice Samuel Stretton, resigned. Also Deputy Medical Officer to the Kidderminster Union.  
**STRETTON, SAMUEL, M.R.C.S., L.S.A.Lond.,** has been appointed Honorary Consulting Surgeon to the Kidderminster Infirmary.  
**WEBBER, WILLIAM W., M.R.C.S., L.R.C.P. Ed.,** has been appointed Medical Officer to the Nos. 1 and 2 Crewkerne Districts of Chard Union.

## Births, Marriages, and Deaths.

### BIRTHS.

**BOWEN.**—On the 25th ult., at Kirkley, South Lowestoft, the wife of Edward Bowen, M.R.C.S., of a son.  
**BRUCE.**—On the 25th ult., at Alva-street, Edinburgh, the wife of Alexander Bruce, M.B., of a son.  
**CURGENVEN.**—On the 1st inst., at Friar Gate, Derby, the wife of Dr. W. G. Curgenven, of a son.  
**SWAINE.**—On September 25th, 1892, at Ranches, Chota, Nagpore, Bengal, the wife of Surgeon F. R. Swaine, M.B., Bengal Medical Service, of a daughter.

### MARRIAGES.

**BIGGS-HOPKINSON.**—On the 28th ult., at the Church of the Holy Trinity, Taunton, John Maundy Biggs, L.R.C.P., of Child's-hill, N.W., son of J. G. Biggs, Esq., of Dailington, Sussex, to Florence Elizabeth, second daughter of the late T. B. Hopkinson, Esq., of Newaden, Middlesex.  
**FIELD-BURT.**—On the 2nd inst., at St. Stephen's Church, Hampstead, by the Rev. J. Kirkman, Vicar, assisted by the Rev. J. P. Flood, Chaplain of Guy's Hospital, Alfred Field, Esq., of Leam, Leamington, to Margaret Elizabeth Burt (of Guy's Hospital), eldest daughter of the Rev. J. T. Burt, Rector of Stoke Doyle, Oundle, Northamptonshire.  
**GRIFFITH-ROBERTS.**—On the 21st ult., at St. Marylebone Church, J. T. Griffith, L.R.C.P., L.F.P.S. Glas., of Llwyn-onn, Penygroes, North Wales, to Harriet Annie, youngest daughter of the late John Roberts, of Marylebone.

### DEATHS.

**BURROWS.**—On September 27th, at Rangiora, New Zealand, W. A. Burrows, M.R.C.S., eldest son of the late William Burrows, M.R.C.S., of Ilington, from injuries received in a carriage accident, having survived his wife twenty months.  
**CROSS.**—On the 3rd inst., at Nile Cottage, Gillingham, Chatham, Alexander Cross, Deputy Inspector-General of Hospitals and Fleets, aged 77.  
**DEAZLEY.**—On the 22nd ult., at Skelga, co. Tyrone, Charles Deazley, M.R.C.S., of Milford Haven, aged 64.  
**HANKS.**—On the 3rd inst., at Mile-end-road, E., Henry Hanks, L.R.C.P., M.R.C.S., L.S.A.Lond., aged 54.  
**LAWRENCE.**—On the 30th ult., at Claverton-street, Bath, Geo. Edgar Lawrence, L.R.C.P. Lond., M.R.C.S., aged 82.  
**O'FARRELL.**—On the 25th ult., at Tangier, Boyle, Ireland, Harvard O'Farrell, M.D., F.R.C.S.I., J. P., aged 71.  
**SARJEANT.**—On the 28th ult., at Eardley-crescent, West Brompton, Arthur Sarjeant, F.R.C.S., aged 68.  
**SMITH.**—On the 30th ult., at Retford, Frederic Smith, M.R.C.S.E., L.S.A., late of 730, Old Kent-road, London, aged 43 years.  
**WILSON.**—On the 30th ult., at Percy Lodge, Sandown, I. of W., William Samuel Wilson, L.R.C.P. Lond., M.R.C.S., son of the late Frederick John Wilson, aged 43.

## Medical Diary for the ensuing Week.

Monday, Dec. 11.

LONDON OPHTHALMIC HOSPITAL, MOORFIELDS.—Operations, 1 A.M. each day, and at the same hour.  
WESTMINSTER OPHTHALMIC HOSPITAL.—Operations, 1½ P.M. each day, and at the same hour.  
OPOLITAN FREE HOSPITAL.—Operations, 2 P.M.  
ORTHOPÆDIC HOSPITAL.—Operations, 2 P.M.  
ARK'S HOSPITAL.—Operations, 2 P.M.; on Tuesday, 9 A.M.  
CAL SOCIETY OF LONDON.—8.30 P.M. Mr. Richard Davy will exhibit his Invalid Carriage.—Mr. Walter Pys will show the Subject "A Hairy Mole treated by Transplantation of Skin.—Mr. Rose will show a Case of Talipes treated by Excision of Tarsal Arch.—Dr. C. Theodore Williams, "On a Case of Bronchiectasis treated by tapping."

Tuesday, Dec. 12.

HOSPITAL.—Operations, 1½ P.M., and on Friday at the same hour.  
MINSTER HOSPITAL.—Operations, 2 P.M.  
LONDON HOSPITAL.—Operations, 3 P.M.  
PROPOLOGICAL INSTITUTE OF GREAT BRITAIN AND IRELAND.—8 P.M. Dr. A. L. Lewis, "On some Flint Implements and Flakes from Cape Blanc Nez (near Calais)."—Mr. A. W. Howitt, "On the Australian Glass Systems."  
J. MEDICAL AND CHIRURGICAL SOCIETY.—8 P.M. Ballot. 8.30 P.M. Dr. Frederick Treves, "On Resection of Portions of Intestine." The paper will be illustrated by diagrams and pathological specimens.

Wednesday, Dec 13.

ONAL ORTHOPÆDIC HOSPITAL.—Operations, 10 A.M.  
DLESEX HOSPITAL.—Operations, 1 P.M.  
ARTHOLOMEW'S HOSPITAL.—Operations, 1½ P.M., and on Saturday at the same hour.  
HOMAS'S HOSPITAL.—Operations, 1½ P.M., and on Saturday at the same hour.  
MARY'S HOSPITAL.—Operations, 1½ P.M.  
DON HOSPITAL.—Operations, 2 P.M., and on Thursday and Saturday at the same hour.  
AT NORTHERN HOSPITAL.—Operations, 2 P.M.  
ARITAN FREE HOSPITAL FOR WOMEN AND CHILDREN.—Operations, 2½ P.M.  
VERSTY COLLEGE HOSPITAL.—Operations, 2 P.M., and on Saturday at the same hour.—Skin Department: 1.45 P.M., and on Saturday at 9.15 A.M.  
NTERIAN SOCIETY.—7.30 P.M. Council Meeting.—8 P.M. Dr. Ormerod, "On Two Cases of Locomotor Ataxy, with Joint Disease."—Mr. R. Clement Lucas, "On Cases of Wounds of Large Vessels."  
CAL MICROSCOPICAL SOCIETY.—8 P.M. Ordinary Meeting.

Thursday, Dec. 14.

GEORGE'S HOSPITAL.—Operations, 1 P.M.  
BARTHOLOMEW'S HOSPITAL.—1½ P.M. Surgical Consultations.  
ARING-CROSS HOSPITAL.—Operations, 2 P.M.  
UTRAL LONDON OPHTHALMIC HOSPITAL.—Operations, 2 P.M., and on Friday at the same hour.  
HSPITAL FOR WOMEN, SOHO-SQUARE.—Operations, 2 P.M.  
RTH-WEST LONDON HOSPITAL.—Operations, 2½ P.M.  
RTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM.—8½ P.M. Mr. Mules: (1) "On a Case of Hydatid Cyst in Orbit." (2) "On a Case of Panophthalmitis from Purulent Ophthalmia."—Mr. Lediard, "On a Case of Ivory Exostosis of Orbit."—Mr. Snell, "On a Case of Hard Chancre at Inner Canthus."—Cases of Central Amblyopia in Diabetes, by Mr. Lang, Mr. Lawford, Mr. Stanford Morton, Dr. Edmunds, and Mr. Nettleship.—Living and Card Specimens at 8 o'clock.—Dr. Samuel West, Sequel to a Case of Optic Neuritis; Mr. Gunn, Case showing Peculiar Appearance in the Retina; Drs. Edmunds and Lawford, Optic Nerve from a Case of Diabetes; Dr. Stephen Mackenzie, Drawings showing Extreme Tortuosity of Retinal Vessels.

Friday, Dec. 15.

GEORGE'S HOSPITAL.—Ophthalmic Operations, 1½ P.M.  
THOMAS'S HOSPITAL.—Ophthalmic Operations, 2 P.M.  
OTAL SOUTH LONDON OPHTHALMIC HOSPITAL.—Operations, 2 P.M.  
ING'S COLLEGE HOSPITAL.—Operations, 2 P.M.

Saturday, Dec. 16.

ING'S COLLEGE HOSPITAL.—Operations, 1 P.M.  
OTAL FREE HOSPITAL.—Operations, 2 P.M.

## Notes, Short Comments, and Answers to Correspondents.

*It is especially requested that early intelligence of local events having a medical interest, or which it is desirable to bring under the notice of the profession, may be sent direct to this Office.*

*All communications relating to the editorial business of the journal must be addressed "To the Editor."*

*Lectures, original articles, and reports should be written on one side only of the paper.*

*Letters, whether intended for publication or private information, must be authenticated by the names and addresses of their writers, not necessarily for publication.*

*We cannot prescribe, or recommend practitioners.*

*Local papers containing reports or news-paragraphs should be marked.*

*Letters relating to the publication, sale, and advertising departments of THE LANCET to be addressed "To the Publisher."*

### PAYMENT FOR MEDICAL CERTIFICATES OF THE CAUSE OF DEATH.

*H. D.*—In the 20th Section of the Births and Deaths Registration Act, 1874, it is enacted "In case of the death of any person who has been attended during his last illness by a registered medical practitioner, that practitioner shall sign and give to some person required by this Act to give information concerning the death a certificate stating to the best of his knowledge and belief the cause of death." This Act, therefore, declares that the certificate shall be signed and given, but makes no provision for any payment to the certifying practitioner. It may, moreover, be inferred that the Act contemplated no such payment being made. At the same time there appears to be nothing in the Act to make such a charge distinctly illegal, although, inasmuch as the certificate must, in accordance with the above-mentioned section, be signed and given, it would be clearly illegal to make the giving of such certificate conditional on payment of such charge.

*Surgeon.*—First by the largest number of votes, or, in the event of the numbers being equal, by priority of registration.

### VICARIOUS MENSTRUATION.

*To the Editor of THE LANCET.*

SIR,—The following particulars may suffice to convince your readers that my case is sufficiently proven as to diagnosis. Mr. E. J. Collins has asked some pertinent questions which might have been inferred by the reader of my previous letter; and being already aware of your limited space, I did not give special details. Curiously enough, just as THE LANCET reached me my case "turned up" again. She says—"It was four months before the bleeding came on out of the eyes that I had seen anything. I have never been regular. What I have seen previously was scanty, but very high coloured. I have never had the same (symptoms) before, but always great pain in the head and very bilious" (pointing to forehead over frontal sinuses); "when I am going to be so I have great pain in the body and legs, and my head is dreadful, and my eyes are very painful, so that I could (implied from her way of expressing herself) bear them to pieces." These are her own words, taken down at the time I now write, and they only serve to confirm my perhaps too hasty diagnosis, according to Mr. Collins. The only difference in her statement appears to be that the menstrual flow, instead of being colourless, as I understood her at first, is high coloured and scanty. Now I asked her this time to state as clearly as possible her symptoms, and she said—"I have a dreadful pain in my head and I am afraid the bleeding will come on again." There is no congestion of the cornea this time, so I asked—"Are you expecting the usual flow?" and she replied—"I am now unwell, but very slight; your medicine did me good last time, and I have come to you for some more." I prescribed some compound decoction of aloes in the same mixture, as she was constipated; and I do not think I shall venture to try hazeline for this affection; it is a remedy, in my opinion, still *sub judice*, and the information Mr. Collins appears to give consists of dubious remarks. A correspondent of a less dubious character informs me that Professor Paget of Cambridge reported a case to the Cambridge Medical Society of a similar character, where a young woman had hemorrhage into the anterior chamber of the eye at each menstrual period, and in addition from the nipples. If your correspondent has any further doubts he had better refer back to your columns, as I have had the misfortune to forget the date when inserted. The watching of this case has rather tended to confirm my diagnosis; and I am perfectly well aware that hemorrhage from the eyes, nose, and mouth may occur from other conditions; but coming on just before, or during the time of, menstruation, without evident cause, would always excite my suspicion in an otherwise healthy subject, especially if the flow were scanty and irregular and the patient virtuous. The bleeding from the eye has not recurred, and I attribute this to timely interference.—I am, Sir, your obedient servant,  
York, December 4th, 1882. G. DE COURCY MORRIS, M.D.

## CEYLON MEDICAL COLLEGE.

A SYNOPSIS of the curriculum in force at the above College for 1882-83 has reached us. Five years of medical study are prescribed, the first three comprising the junior, and the last two the senior, course. In the first year, the subjects include anatomy, elementary chemistry, elements of zoology, practical vaccination, practical pharmacy, clinical medicine and clinical surgery, dissections, physics, botany, and biology. At the end of this year an examination is held in elementary anatomy, botany, physics, pharmacy, and biology for the first professional. The subjects for the second year are anatomy, physiology, chemistry, materia medica, clinical medicine and surgery, hospital practice, and dissections, in all of which subjects a compulsory examination is held. The third year embraces the same subjects as those of the second year, with the addition of surgery and practical chemistry, and at the end thereof the students are examined in anatomy, physiology, chemistry, and materia medica for the junior pass or second professional examination. For the fourth year the subjects are medicine, surgery, operative surgery and surgical anatomy, clinical medicine and surgery, hospital practice, medical jurisprudence, midwifery, and pathology, in all of which a compulsory examination is held. In the fifth year the same subjects are prescribed, with the addition of hygiene, diseases of women and children, practical midwifery, and ophthalmic medicine and surgery. At the end of this year the final examination is held in all the subjects with the exception of pathology, ophthalmology, chemistry, botany, and physiology. Dr. J. L. Vanderstraeten is the principal of the College.

A. M. D.—Our correspondent is thanked for his letter, but we cannot publish it, as he will see that events have turned out very different from his anticipations.

Mr. Robert Hugh Hodgson.—The practitioner referred to has a very honourable degree, though not registrable in England.

## BOLINGBROKE HOUSE PAY HOSPITAL.

To the Editor of THE LANCET.

SIR,—Will you allow me to correct an error of figures in your notice of the second year's report of the work done at the Bolingbroke House Pay Hospital, which appears in this week's LANCET. A critical reader of the notice would ask the question—How is it that with double the number of patients in 1882 as compared with 1881, the cost of each patient has increased? The average weekly cost of each patient for 1881 is wrongly quoted in your notice. It should be £3 5s., not £2 0s. 5d., and as in 1882 the cost has decreased to £2 0s. 11d. the institution has made a decided advance nearer self-supporting point. In fact, the increase of self support by the payments of the patients has been 6½ per cent. This improvement is not the result of increased average payments, for actually there is a slight decrease—£1 10s. 6d. in 1881, £1 10s. 1d. in 1882—but is accounted for by the increased number of cases admitted. This tends to confirm me in the opinion expressed in my first report to the committee in 1881, that "if in the future the patients sufficiently increased in numbers and maintained their weekly average payment of £1 10s. 6d., they will pay their cost." It is desirable therefore that all who are interested in the experiment of providing pay hospitals for the lower middle and artisan classes should help to make the institution known. Its success depends much upon publicity, for treatment in a hospital is not a daily requirement like food and clothing, and people must be taught to remember where to go when sickness comes upon them. The fact that they have so often resorted to charitable hospitals makes the task of teaching them that they should pay for medical treatment according to their means all the more difficult and slow to accomplish. But this reform will be gradually worked out and the "father" of the pay hospital movement, Mr. Burdett, takes much encouragement, I believe, from the results achieved at Bolingbroke House in the second year of its existence.

There is an important element in the scheme for providing pay hospitals and departments which remains undealt with. The small paying power of many patients is the seemingly insuperable difficulty. A large proportion of the applications I receive is from persons who state their willingness to pay seven or eight shillings weekly and plead their inability to pay more. Although I believe that, as a rule, the most people can pay is the least you will take, yet there must be very many who are able only to pay a sixth part of their cost, and the question is whether to admit five-sixths of the charitable element into the scheme. On the other hand, it may be contended that a patient cannot live in the ordinary way outside on seven or eight shillings weekly, and if he can pay no more he is a fit case for a charitable hospital. With sickness wages often stop, and if a patient presents himself saying "I have sufficient laid by to give me a few weeks' treatment in a pay hospital, if you will receive me for seven or eight shillings, and I prefer to pay to being cured on charity," it seems a wrong thing to decline him. Where shall the "charitable" end and the "pay" begin, or shall the two elements combine in one scheme?

I desire to thank you on behalf of Canon Erskine Clarke and the committee for the kind notice you have given of the second year's report of Bolingbroke House, and I shall be pleased to send a copy of it to anyone interested in this important subject.

I am, Sir, your obedient servant,

J. S. WOOD, Honorary Secretary.

Woodville, Upper Tooting, S.W., Dec. 4th, 1882.

## CLOAK ROOMS FOR LADIES.

ON this subject *A Victim* writes to us:—

"The inconvenience, not to say positive suffering, from there being no cloak rooms for ladies in the main thoroughfares and principal streets, is very great. The facilities of getting from place to place in the metropolis, and the vast extent of London, not infrequently take ladies and women of the artisan and working classes away from their homes, either on visits or business of one kind or another. The railway stations are few and far between. In Paris, cloak rooms are to be met with in all the main streets. Birmingham is similarly favoured. But here in London such places are positively unknown. Affections of the bladder or kidneys make the want of these places almost an agony, and impossibility of getting relief when needed must induce disease. Can nothing be done in this matter? It is truly a great need."

Mr. A. Aitken.—Where the widows and orphans of medical men are not easily able to pay for medical services, it is customary for medical men to attend them gratuitously.

Dr. J. A. Campbell.—In an early number.

## IMPERFORATE ANUS.

To the Editor of THE LANCET.

SIR,—The above being by no means rare, I forward particulars of the case on account of what was revealed at the post-mortem, and would be glad to know if any of your readers have heard of or seen a similar case.

I was called to attend Mrs. P—, in her third confinement, about 12 A.M., on Oct. 7th, 1882, but was unable to be present until 1.30 P.M. When I arrived the birth of the child (male) was just terminating. This was followed by a rush of liquor amnii, a great quantity of which the child received into its lungs, almost completely suspending respiration. Artificial respiration was kept up for some time, and breathing established, which was however a good deal embarrassed by the quantity of fluid still remaining in the lungs. On examining the child, the anus was imperforate. Immediate interference not being demanded, the case was left till next day, instructions having been given to keep up respiration. However, during the night the child died.

By permission of the father, Dr. Shirliff (my principal, who was interested in the case) and I held a post-mortem. The rectum was found very much distended, lying deeply in the perineum, but no opening could be made out. A probe was introduced into the urethra, and, passing through a slight constriction, was found in that portion of the bowel which had been dissected out. Not being able to introduce the probe into the bladder, the abdomen was opened, without however finding that organ. The ureters were dissected out, and a bristle passed down was found in the rectum close to its junction with the urethra, clearly proving the absence of a bladder. All the other organs appeared normal. The nurse informed me the child had passed a very dark-coloured fluid which stained the napkins.

The immediate cause of death was no doubt due to the presence of such a large quantity of liquor amnii in the lungs, every effort having been made by the nurse to keep up respiration.

I am, Sir, yours truly,  
JNO. P. TOPPING, M.B., C.M. Glasgow.

Kingston-on-Thames, Nov. 1882.

Mr. Geo. Wm. Ayres.—The circular has been mislaid. We should be glad of another copy.

Surgeon-General Cockburn.—Next week.

## SUCCESSFUL GASTROTOMY IN JAPAN.

To the Editor of THE LANCET.

SIR,—I found the following remarkable account of a unique and scarcely credible surgical feat in a copy of the Hongkong *Overland China Mail* sent to me the other day. Considering the great interest and importance of the operation of gastrotomy, and the prominence it has recently assumed, I thought it might not be uninteresting to your readers to bring before them this tale of operative triumph from the Land of the Rising Sun. Albeit there is a smack of the fabulous about it, there is no reason to deny its authenticity.

I am, Sir, yours faithfully,

D. BEATTIE BAIN, M.B., C.M.

Tay-street, Dundee, November 27th, 1882.

"The *Choya Shinbun* tells an extraordinary story of skill and courage on the part of a Japanese doctor. It runs to the effect that one morning, as a certain man named Ito was cleaning his teeth, by some means or other he let his tooth-brush slip down his throat. Medical assistance was at once procured, and the unfortunate man, who was suffering the acutest agony, drenched with purgatives, but all to no avail. It was not till the fifth day that a certain Dr. Hashimoto, principal of the highest medical college in Tokio, was called in. Dr. Hashimoto said there was just one chance to save the man, and as the case was desperate it might as well be tried, for the patient would certainly die, and that almost immediately, if nothing was done. The friends consenting, chloroform was administered and two deep incisions were made cross-wise in the man's body. The stomach being laid bare, it was discovered that the tooth-brush was deeply embedded in it, and that, one edge of the handle being sharp, it had worked its way half through. The thing was speedily extracted, and the two wounds, inner and outer, deftly sewn up by the operator, who is said to have won immense renown by the success which crowned his efforts. The *Choya Shinbun* adds that the man to whom the accident occurred is now in a fair way of recovery."

## JOURNALISTIC ECONOMICS.

WE have to congratulate our military contemporary, the *United Service Gazette*, upon its discovery of the important principle of how to carry on a journal on truly thrifty principles! The week before last it copied one article, and last week two articles, from THE LANCET *verbatim et literatim* from beginning to end without the slightest acknowledgment of the source from which they were taken. *Proh pudor!*

N. E. R.—Bones are undoubtedly of value as a food, and their comparative cheapness is overlooked; but we doubt whether the plan suggested of utilising them for dietetic purposes would answer commercially. The nitrogenous material of bone being ossein, a gelatine, it would have to be supplemented largely with some albumen before it could be available as a constant food supply.

## GAS FIRES.

To the Editor of THE LANCET.

SIR,—In my practice as an architect I have from time to time recommended the use of open gas fires, not only from their convenience and cleanness, but because, when more universal, their use will at least assist in abating the intolerable smoke nuisance arising from the ordinary open grate. I have three or four open gas fires in my own house. I am now informed, upon high medical authority, that these fires are most harmful. In a case which has recently come under my notice the gas fire (one of Verity's) has been instantly ordered out of the room, and in the same grate is now burning a coal fire.

The question I would ask is as follows:—Given a good grate and free updraught, is the heat radiated from burning coal harmless, and the heat radiated from asbestos, warmed by an atmospheric burner, dangerous? I write as a layman, not understanding these things, but feeling that a qualified opinion in the matter must be of great value, and I know not how to obtain this except through your columns.

Dean's-yard, S.W., Dec. 1st, 1882.

I am, Sir, yours obediently,  
SOMERS CLARKE.

\*\* Provided that there are efficient arrangements for the escape of the products of combustion, there is no objection on the score of health to the use of gas fires. We have known instances of these fires being fixed in ordinary grates, and in order to increase the amount of heat given off from them the register has been closed. This, of course, is inadmissible.—ED. L.

Mr. A. F. Blagg.—A medical man is not bound to attend unless summoned or ordered to do so by the coroner. A house-surgeon is not entitled to a fee in respect of cases dying in the infirmary.

Surgeon.—The coroner has a discretionary power. But, alas! he has not always discretion, and so the office is brought into serious disrespect.

J. H. (Newington).—1. No.—2. Yes.

## ASSISTANT MEDICAL AND SURGICAL OFFICERS AT HOSPITALS.

To the Editor of THE LANCET.

SIR,—Allow me, as an old subscriber to and correspondent of THE LANCET for above forty years, to endorse your remarks of Nov. 18th as to the propriety and necessity of appointing assistant medical and surgical officers to all large hospitals, metropolitan or provincial. The proposal was made by me to the Board, staff, and subscribers to the Leeds General Infirmary above thirty years ago, but the suggestion was declined and ignored, though I proved by numerous statistics published at the time from the history of the largest hospitals at home and abroad that the appointment of assistant medical and surgical officers to do the work and take the place of worn-out seniors, when too much occupied with private practice, would be a benefit to the charities, the poor, the public, and the profession.

I am, Sir, your obedient servant,  
J. INGHAM IKIN, F.R.C.S.

Park-place, Leeds, November 23rd, 1882.

Mr. H. B. Gilmour might with advantage consult the series of articles on Hospitals, written by Dr. Mounat, and published in THE LANCET, vols. I. and II., 1881.

Enesia.—The continuous galvanic current is the only one likely to be of service in such a case.

## PUERPERAL SEPTICÆMIA.

To the Editor of THE LANCET.

SIR,—In your last issue you referred to a letter you had received from a correspondent on the prevalence of puerperal septicæmia in the practice of provincial hospital surgeons practising midwifery and the rarity of such cases in the practice of those unconnected with a hospital. I have repeatedly noticed the same thing, and have asked many practitioners unconnected with a hospital, both in my neighbourhood and elsewhere, whether they have had any cases of puerperal septicæmia. Their reply in every case has been in the negative. I should like to see the subject ventilated in your columns, as I think, with many others, that it is a very important one, and no party feeling, which you seem to think actuates the motives of your correspondent, should be mixed up in the matter.

November 8th, 1882.

I am, Sir, yours respectfully,  
FIDMS.

## MEDICAL ADVERTISING IN CEYLON.

An advertisement has reached us showing that the art of advertising one's self by advertising one's book is not confined to a few members of the profession at home, but has a strong illustration in Colombo in the case of a long advertisement of a book on Diseases of Children, the contents of which are stated in a fashion the most likely to attract the eye and strike the mind of that "herd confused," the people. Such practices will be duly judged by the profession of Ceylon.

Dr. P. O'Connell (Sioux City, Iowa, U.S.A.).—Written memoirs for the Prix St. Paul may be signed by the author or not, as he may please. If not signed, they must bear an epigraph, and be accompanied by a sealed envelope, enclosing the author's name, and with the same epigraph written outside.

## DISLOCATION OF THE SHOULDER.

To the Editor of THE LANCET.

SIR,—The daily routine of duties devolving on medical men in large general practices prevent, to some extent, their keeping themselves as thoroughly acquainted as could be wished with all the recent additions and improvements to surgical and medical literature; so that one's LANCET, or some other weekly periodical, comes to be looked forward to to keep us up to the current opinions, &c., of the day.

In this way THE LANCET for Nov. 4th last gave me a "wrinkle" for reducing a dislocation of the shoulder in the manner explained by M. Kocher, and on Wednesday last, Nov. 29th, I had an opportunity of testing, if I may say so, its value. A married man of about twenty-six years of age, of slight build, but fairly muscular, called on me, having had a fall off a tricycle, injuring his right shoulder. There was no great difficulty in diagnosing sub-coracoid dislocation. I sent him home and followed him there, and, after removing his clothes, I attempted the reduction by means of the heel in the axilla. He did not bear the pain of this at all well, so without further delay I proceeded to try M. Kocher's method, and, following his instructions, in less than two minutes we each felt and heard the head of the bone slip back into its place, and I must say I was highly gratified with the ease and simplicity with which it was reduced; and I should certainly recommend it to any of my fellow practitioners in a like case.

I am, Sir, yours very truly,

Queen's-park, Harrow-road, Dec. 4th, 1882. A. L. GRIFFITH.

Dr. Andrew Wilson (Edinburgh) is thanked, and his offer shall be borne in mind.

General Practitioner.—Certainly not.

## CASE OF STRAMONIUM POISONING.

To the Editor of THE LANCET.

SIR,—With reference to Dr. Wigg's remarks on the case of poisoning by stramonium, reported by me in THE LANCET for Nov. 4th, will you allow me, in the interests of toxicology, to point out that where the term "berries" was used it was obviously as a quotation from the history supplied by the friends, the ordinary name, "thorn apple," occurring later on; and, in the second place, that it was the absence of the symptom of dryness of the throat which was commented upon. With regard to the identification of the poison, I may suggest that the seeds of stramonium are quite easily recognised. I must apologise for troubling you with these remarks, which would have been unnecessary had the communication been more carefully read.

I am, Sir, yours faithfully,  
ALFRED LONDON, M.D.

Bristol Royal Infirmary, December 2nd, 1882.

A Subscriber to The Lancet.—We have no means of preventing the printing of extracts by local newspapers.

## CLINICAL THERMOMETERS.

To the Editor of THE LANCET.

SIR,—Within the last month I have burnt the bulb of two clinical thermometers. I presume it is caused by sitting too near the fire and exposing it to a heat of more than 115°. I carry my thermometer in the usual metal case in my waistcoat pocket. I have no doubt but the same accident will have occurred to other professional brethren. Can any of your readers offer any suggestions by which this mishap may be prevented?

December 6th, 1882.

I am, Sir, yours, &c.,  
M.D.

## DUTIES OF SHIP SURGEONS.

To the Editor of THE LANCET.

SIR,—Will you kindly allow me to ask, through your columns, the kind of life led by a ship's surgeon on the Royal Mail Steam Packet Company's boats going to Jamaica and the neighbouring islands, giving an idea of how the day is spent, the duties of the surgeon, the accommodation, places where the ship touches, and the time away.

I am Sir, yours truly,

T. R. ALLINSON, L.R.C.P. Ed.  
Kingland-road, E., December 4th, 1882.

## SPANISH MEDICINE AND SURGERY.

To the Editor of THE LANCET.

SIR,—Will someone inform me where in London I can obtain books on Medicine or Surgery in the Spanish language?—I am, Sir, yours, &c.,  
December 6th, 1882. ESPANOLA.

THE  
"Bradshawe" Lecture  
ON

## SOME RARE AND NEW DISEASES.

*Delivered at the Royal College of Surgeons of England  
on December 13th, 1882,*

By SIR JAMES PAGET, F.R.S.

MR. PRESIDENT AND GENTLEMEN,—It is my first duty, delivering the first Bradshawe Lecture in our College, to offer a tribute of respectful thanks to the generous lady by whom it was founded, the widow of Mr. William Wood Bradshawe, a Fellow of this College, who practised at Dover and at Reading, and died in 1866. He was a me-loving and studious man, who diligently cultivated his mind in both literature and science, and his widow, who revived him fourteen years, being desirous to testify her attitude for the happiness which she owed to him, bequeathed a thousand pounds to this College, and as much to the Royal College of Physicians, on the condition that each should institute a lecture, to be given annually and to bear his name. She desired that the lecture should be on some subject connected with medicine or surgery, and that the choice of the lecturer should rest with the President of each College for the time being. She made no stringent regulations, and seems to have wished only to maintain her husband's name in good repute by associating it with the advancement of the science which he loved.

In my endeavour to fulfil her exemplary wish, I have chosen the subject of Some Rare and New Diseases. I hope to be able, in speaking of them, to illustrate a part of the natural history of disease which I think is too little studied—that part, namely, which relates to the variations and the combinations of diseases in hereditary transmission. Besides, both in the choice of its subject and in the whole enterprise of giving this lecture, I have looked for an opportunity of promoting pathology by promoting pathological museums, a motive which I am sure will be pardoned, though I am conscious of its being in some measure personal, for I have spent so much time and thought in museums, that I feel as, in their greater utility, I should myself become more useful.

Now, first, respecting rare diseases, there may seem no want of opportunities of studying them. Our journals and the proceedings of our societies are full of the records of rare cases; many collections of such cases have been published, and here are many rare specimens in every museum. All these have that kind of attraction which belongs to everything that excites our wonder, but we too seldom let the wonder have its proper consequence; we too seldom let it provoke our curiosity so far as to make us search for the meaning and reason of the rarity. There is a question which we should often ask ourselves, Why is any disease rare? at least, why is any rare which does not depend on some accident or some rarely occurring external cause? I shall try to suggest answers which may be, in some instances, efficient; but I fear that, in more instances, if I can be useful at all, it can only be by suggesting how answers may be found.

First, there is a difference, though it may often seem only verbal one, between rare cases and rare diseases. A case may be called rare when, though it is evidently one of a common disease, it differs from the usual type or standard of that disease in some one or two features. Thus it is a rare case when a common disease is found in an unusual place; as an epithelial cancer on the upper lip, or this fatty tumour on a finger; or in unusual quantity, as in this large articular tumour on a femur; or, again, a case may be rare in respect of the time of its occurrence. For instance, I have lately seen cancer of the rectum ending fatally in a child of eight years, and scrofulous abscess in a man of eighty; and many of us must have seen instances, though they are rare (and these are very important in the history of diseases), in which manifestations of syphilitic inheritance, usually

evident in infancy, have not appeared till the time of youth or even of adult age; or cases may be very rare in respect of accidental complications or of the absence of some usual symptom. But of all these and other rare cases the number and variety are so great that it would be impossible to deal generally with them, except as with mere story-telling. It would be very useful if someone would collect hundreds or thousands of them, and arrange them, even though it were only under such headings as I have just indicated. But even as they are singly and in disorder, let me say that we ought not to set them aside with idle thoughts or idle words about "curiosities" or "chances." Not one of them is without a meaning; not one but might be the beginning of excellent knowledge, if only we could answer the question, Why is this rare? or, being rare, why did it in this instance happen?

But, because of their number and variety, I must pass by rare cases and will speak only of some rare diseases—that is, of some diseases which are rarely seen and yet occur in a sufficient number of cases, and with sufficient uniformity, and sufficient difference from other diseases, to permit of their being described in general terms, and to justify their being called by distinctive names. And of these again, for they are numerous and various, I shall select only that group which seems most attractive; the group of those, namely, of which there seems reason enough for believing: First, that they were, lately, new diseases and have become more frequent; and, secondly, that they are due mainly to morbid conditions changing and combining in transmission from parents to offspring. I say due mainly. It is certain that changes in the external conditions of our life have influence on even those morbid conditions which are most personal; but this influence is very hard or impossible to trace in the cases which I have in mind, and it may to-day be neglected though not forgotten. For, in all these cases, the personal factors and those of which alone I have to speak are more potent than the conditional, the inner than the outer. We call these diseases constitutional, diathetic, or by similar names; but the chief fact in them is that they, or the necessary previous states or predispositions to them, are inborn and inbred.

Let me first show that there is reason enough for believing that some rare diseases of this kind were recently—say within the last century—new; and that more recently, though still rare, they have become more frequent. There is, I know, a general unwillingness among pathologists to admit that there are new diseases of this kind; and this unwillingness is often just, for many diseases that may seem new have probably existed long and been overlooked; they may be new to knowledge, but not new in fact. Bright's disease and Addison's disease were new in the sense of having first been well observed and described by those whose names they bear; but no one would venture to say of diseases so difficult to detect, as these used to be, that they did not exist long before they were well observed. We could as well believe that embolism never occurred till just before it was found out, or that right-side hemiplegia used not to be associated with aphasia. These things were old before they seemed to be new; but how long they had existed neither records nor museums can tell. It would be, indeed, very interesting if we could tell the time and manner of first appearing in the case of many diseases which are now common; but it is scarcely ever possible. And yet, if you will allow me a digression, let me show what in some instances museums may supply, and what I hope they will in the future supply much more largely. Here are specimens of typhoid ulcers of the intestines preserved by Hunter. Few things have been more important in the knowledge of fevers than the clear proofs of the distinction between typhus and typhoid given by Sir William Jenner in 1850. It was one of the best life-saving discoveries of this century; before it both diseases were at least partially misunderstood, and neither was so well treated as now. Since the distinction between them was discovered it has been possible to trace in old recorded cases probable instances of both; but there is nowhere so clear evidence of the occurrence of typhoid a century or more ago as is given in these specimens of Hunter's preserved without name or history; not unobserved, and yet not in any fair sense understood. Now in this, as in many things, Hunter set us a good example. He did not think those things unimportant which he did not understand. He was a thorough naturalist, and kept specimens of everything in his field of study which, though not yet, might become useful.

But, however much of what seems to be new we may justly ascribe to our previous oversight of what was old,

there yet seems to be evidence enough that new diseases are in progress of evolution, and that, as I have said, some of the rare diseases of which I have to speak are the earliest instances of the new. Good evidence of this kind is to be found, I believe, in the peculiar joint-disease discovered by M. Charcot in association with locomotor ataxy, and in the disease of bones to which I have given the name of osteitis deformans. Neither of these, I believe, was described till within the last few years. They may have been overlooked, but to believe this we must believe what is very improbable. We must believe that all the most acute and observant practitioners before our time overlooked, not merely obscure and transient diseases, difficult to study, but cases which lasted many years and gave constant great distress, and were manifested in signs so plain that they could be recognised in the shape and gait, in the posture and whole aspect of the patients, in strangely large heads and curved limbs. And, further, we must believe that the morbid anatomists before ourselves overlooked changes of structure of the largest, most obvious, and most striking kind. It is, surely, very unlikely that they who studied and recorded such cases as those of extreme rickets and mollities ossium, and even called it rachitis adulatorum, should have left unnoticed the cases of these two equally and somewhat similarly disfiguring and damaging diseases. This great improbability is strengthened by that which I believe to be a fact—that we have none but recently collected specimens of either of these diseases in our museums; not even among the crowds of bones and joints collected by our predecessors.

In twenty-six years I have seen twelve well-marked cases of the osteitis deformans, and about as many in which it was only partially evident. In the last six of these years I have seen seven of these cases, and others have been published, and yet I cannot find evidence that the disease was ever seen by any of those who had practice like my own; Brodie and Stanley, who saw as many cases of diseased bones as any surgeons of the last generation, had seen no case but that which I showed them more than twenty-five years ago in the patient from whom these specimens were taken. Moreover, I cannot find an old specimen in our museums, or a representation of one in any book of plates, or a description of one in any catalogue. This might not seem very strange in the case of specimens troublesome or expensive to keep, or in such as are said to "show nothing." But these are very striking deviations from health, very plainly to be seen, and dry bones are neither costly nor troublesome to keep. We have large numbers of them collected by Hunter, Howship, Langstaff, Liston, Cooper, Stanley, and others, who collected not merely illustrations of diseases well known to them, but whatever was curious, whether it were understood or not. They would have looked on these bones as gems.

I might repeat this statement in nearly every particular concerning M. Charcot's disease. I believe there is not an old specimen in our museums. There is not one in the Musée Dupuytren; I cannot find a notice or an illustration of one. And yet this disease is now so far from being very rare that Dr. Buzzard has had nine cases under his eye at one time, and several have in recent years been shown in our societies.

Let me adduce one more instance of what I believe to have been new diseases within this century, though the museum evidence is not so strong as in those of which I have been speaking. Many believe, and, I think, quite rightly, that instances of typical gout, such as gained for it the name "podagra," have lately become comparatively rare, and that a large number of less acute diseases, regarded as forms of incomplete or suppressed gout, are much more frequent. It may be that some or many of these lesser forms were always as common as they are now, but were overlooked or were not distinguished from other similar ailments. But here is a specimen of the effects of phlebitis of the femoral and external iliac veins, which, with its history, may tell that gouty inflammation of the veins was, fifty years ago, if not a new disease, yet a much rarer one than it is now. Sir Henry Hallford saw as much of gout, I suppose, as any man that ever lived; for he was for many years, during a very luxurious period, in the largest practice among the richest people in this town. He gave an account in 1832 of what he called phlegmasi dolens in the male. The disease so-called was common and well-known in women after parturition; so that, to justify his essay as a record of cases hitherto unobserved, it was enough for him to speak of phlegmasi dolens as occurring in men. He speaks of it as having been not long before regarded as "immediately occasioned by a

deposit of milk"; but that "being tested by a more exact pathology," it was now attributed to "an inflammation of the veins of the pelvis." And he says, "he was much mistaken if he had not seen three instances of it" in men "within the last few years." He then relates the case of the nobleman from whom, several years afterwards, this specimen was taken by Sir Astley Cooper—an admirable example of phlebitis, which we may be nearly sure was gouty, showing the changes in the blood-clots and in the walls of the veins during many years.

At the present time, phlebitis of this kind in the male can scarcely be called a very rare disease. There are few, I imagine, in large practice who have not seen many more than three cases within the last few years. So, we may believe, I think, that the disease has become more frequent in the last fifty years; and may suspect that not long before Sir Henry Hallford's time it may have been a really new disease. It is hard to believe that it could have been overlooked. Its characters are strongly marked and evident to both eye and touch; it is a very painful, disabling, long enduring disease, often recurring, sometimes observed in several members of the same family, and commonly leaving the affected limb large, heavy, and clumsy for many years. Could this have been overlooked when similar limbs, in consequence of an allied, though not the same disease, were known and described in women, and while, as it happened, the subject of phlebitis, in its traumatic and pyæmic forms, was being very carefully studied? For there was a form of phlebitis much more common in the last century than in this; the phlebitis that occurred after bleeding. Hunter had studied this very carefully, had written on it, and shown it in these specimens; and after him, both this and the phlebitis after amputation were well known. Especially after the beginning of this century the phlebitis after amputation was thoroughly worked at. It was only three years before the publication of Sir Henry Hallford's essay that Mr. Arnott's renowned paper on inflammation of the veins was published in the *Medico-Chirurgical Transactions*. In the same volume are the chief papers by Dr. Robert Lee on phlegmasi dolens; and he describes cases of phlebitis associated with pelvic cancer; but not one spontaneous phlebitis is mentioned by either of them.

Now, I think that in all these facts there is enough, not, indeed, to prove, but to justify the belief that we have here examples of diseases which have appeared in this country for the first time within the last century, and which have since become sufficiently frequent, and acquired sufficiently constant and distinctive characters to be described in general terms and called by new names. Let me repeat; these are not diseases hard to be discerned. They are so well-marked, so distressing, so long enduring, and both during life and after death so large and distinct in all their characters that it seems impossible that, unless they were very much rarer than they are now, they could have been overlooked.

I think it probable that there are other examples of the like kind; but I do not know them, and would rather go on to the second part of my subject—namely, to show the probability, or, at least, to justify the hypothesis, that these diseases are among the instances of the results of morbid conditions, changing and combining in transmission from parents to offspring.

It should hardly be necessary to argue that changes of type in inherited diseases—changes which may be compared with the variations of species or of varieties in natural history—do take place. Yet I venture to think that many of us are prone to think too little of these variations; to regard them as rather unmeaning exceptions, or as the results of some unusual external conditions diverting diseases from their customary course.

It will be better for us if we study, in pathology as in natural history, varieties as much as species; changes as well as more stable forms. Types of disease there are, standard forms, and the tenacity with which they are maintained—some, even, from pre-historic times—in all the varieties of the conditions of our lives is one of the most remarkable facts in all pathology. But they are not unalterable. Types vary in diseases, as in species; even in the diseases which depend least upon external conditions, and most on the qualities which are transmitted by inheritance.

Let me give some reasons why this must be.

1st. An exact likeness is never transmitted by inheritance; neither an exact likeness of either parent, nor an exact composite of both. This is evident enough in features, size, weight, and all that we can observe in external things.

we could be exactly endoscopic we should observe equal variation within; the same want of exact likeness in liver and lung, and, I venture to say, in blood and lymph and plasma, and whatever goes to make up the whole person, healthy or diseased. The inheritance of likeness in disease, or liability to disease, is, indeed, clear evidence of the transmission of likeness in the very minutest structure and composition. If the likeness is never perfect, it may in different persons vary in this way or that; it may vary towards disease or away again towards the healthy type; but it is never perfect, and in successive generations its degree of unlikeness may increase to a great width of difference.

2nd. The certainty and probable extent of this variation must seem the greater if we consider the mingling of diseases, and of all dispositions and liabilities to diseases in transmission from and through both parents. Consider the difficulty of maintaining the "breed" in any of the varieties of the species domesticated or cultivated by us, in horses or dogs, in pigeons or in seedling plants; the care that both parents should be of the same blood, or the same race, and at their produce should be raised in all due conditions; and then consider how numerous and wide, in spite of all this care, are the deflections from the type. With these facts before us we cannot imagine that diseased conditions should not be transmitted singly and unchanged; it is, surely, not likely that disease should be transmitted with more perfect conformity to type than normal compositions are. Hybrids and mongrels must be even more common among diseases than among species and varieties.

3rd. And, in thinking of the variation of diseases by combining or convergence of inherited qualities, we may not limit our thoughts to a single generation. It is reasonable to believe that instances occur of reversion, in which diseases or tendencies to disease may appear after a lapse of many generations. Such, I expect, are some of the cases in which prosy has been seen, even of late years, in this country in persons never exposed to any of its external causes; and to be like of this we may refer, I think, some of the rare cases which defy all efforts to refer them to any combination of types of disease now prevalent.

Now, I half wish that I could escape from the necessity of stating my doctrine by my facts; but as I have often asked myself, so others may ask, how can the cases of rare diseases which I have been speaking, be explained as the results of morbid conditions changing and combining in transmission from parents to offspring. In the phlebitis we may often trace a variation from the customary type or standard of the very old and heritable disease, gout. In many cases its relations to typical gout are clear. The patients are members of gouty families, and in many of them other signs of gout are evident, either coincidentally with the phlebitis or at other times; it has, in short, all the evidences of being one of the many forms of what is called "incomplete gout." But, for a reason why this variety of gout settles (if I may so speak) in veins, especially in those of the lower extremities, I can only guess at a convergence of inherited dispositions both to a modified form of gout, and to some condition of veins rendering them, among all the structures, the most sensitive to the gouty process. Certainly it is not accident which determines the disease to the veins, for this disease "runs in families." I know of its occurrence in two brothers and three of their cousins; and I have heard Sir Charles Locock tell of four sisters who had phlegmasia dolens and whose father had crural phlebitis.

I am conscious that this is little more than guessing, and for the osteitis I must guess still further; or, rather, let me say that, to the furthest bounds of propriety, I must exercise that use of the imagination which may happily discern a way towards the truth. I imagine, then, that a likeness of the osteitis deformans to several other diseases may indicate a combination, in definite proportions, of transmitted dispositions to those diseases; a combination which has become possible by changes of the type of one or more of them. First, it shows some relationship to mollities ossium and rickets, for, though it is an inflammatory disease, which they are not, yet the softening which permits of the curving of the bones is distinctive, and hardly occurs in any other form of inflammation of bone in middle or later life. And, again, the relation of the osteitis to rickets and mollities ossium is notably indicated in the porous thickening of the skull, which is found in some instances of them all, and which is well marked in our specimens of genuine rickets from erroneous diet in young lions and young monkeys. Further, there appears some relation to gout, for some

of the cases have known inheritance of gout, and instances are sometimes seen, in typically gouty persons, of a single bone having all the characters of the osteitis, though all the other bones appear healthy. Such a one is this femur, for the opportunity of showing which I am indebted to Mr. Bowlby of St. Bartholomew's. There is a likeness, also, it may be said, to the osteo-arthritis and other forms of rheumatic gout in the remarkable maintenance of good general health during even many years of a painful and crippling inflammatory disease; and, further, there appears some relationship to cancer in the singular frequency with which cancer or sarcoma occurs in the healthy bones or other parts of those who have suffered for many previous years with osteitis deformans.

Thus, I imagine, by inherited dispositions, accumulating and combining or converging in definite proportions, this disease may be produced. I would try to imagine the genealogy of M. Charcot's disease, but that I have too little clinical knowledge of it. I can only suggest a combination of osteo-arthritis with syphilis chiefly localised in some spinal nerve centre; but I believe far better suggestions may be made by those who, suspecting a combination of diseases rather than many radiating from one source, will carefully study the essays of Professor Charcot and Dr. Buzzard's admirable clinical lectures on Diseases of the Nervous System. Besides, I may seem to have guessed already more than enough. Let me, therefore, say that even if my guesses are wrong, my error cannot weaken the probability of the belief that these and other rare diseases of like kind are instances of settled varieties of diseases, severally due to variations and convergence of morbid conditions in hereditary transmission. And if this be in any measure true, or even not more than a reasonable hypothesis, then it must be of great importance that we should know much more than we yet do of the variations which, in progress of time, diseases, or certain examples of them, may undergo; of their deviations in a gradually increasing number of instances from typical or standard forms; their acquirement in those instances of other comparatively fixed and long-abiding characters; of the occasional disappearance of old forms of disease, and the evolution of new ones. Such variations in diseases should be studied as Darwin studied the variations of species. Let me be clear in saying, as Darwin studied; for in the pursuit of new knowledge he may be a model to all, as he has been to me so far as I could imitate him. He, as I know, would have studied these things, not by deduction, as from a law exactly formulated and from which he could trace the course of every change, but by a most careful collection of facts, facts to be seen in specimens and read in full records, and stored in museums, and by a study as complete for every case as if no law of evolution had ever been discovered.

Let me add that the study of these variations of diseases is not one of mere pathological curiosities. It may be of great practical utility; let me show how, if only that I may provoke some to pursue it vigorously to whom mere pathology is not attractive. We hear much, and often, of the uncertainty of medicines; of disappointments in the use of this or that supposed remedy; and substances which have long been in good repute for the treatment of this or that disease are spoken of with disrespect. It need not be questioned that in many cases the belief in the utility of a medicine has been maintained by completely erroneous observations. Such was the belief in the utility of infinitesimally small doses of anything ever yet swallowed. And other beliefs less evidently absurd may have been nearly as ill-founded. But there are many of which this is not to be said. It cannot be doubted that bromide of potassium is often very useful in epilepsy; yet sometimes, as we say, it fails; or that guaiacum is useful in some cases of chronic rheumatic arthritis, and is in others very disappointing; or that arsenic sometimes does and sometimes does not do good in cases of lymphadenoma. I suppose there is not a medicine in the pharmacopœia which does not sometimes disappoint him who gives it hopefully; not one which is not, therefore, spoken of with contempt or blame, as if it were a responsible agent convicted of default. But here is an unfair imputation. It is not these medicines which are in fault but ourselves. That which some call the fallacy of therapeutics is generally the fallacy of diagnosis. To state the facts roughly, we suppose cases to be alike which are really different; and, very naturally, the medicine that does good in some of them is useless in others. For example, in the group of cases which I chiefly have in view, we do not

always discern when a disease has varied so far from its usual type that it is no longer amenable to its usual remedies. A better diagnosis must precede a better therapeutics. We need not only the diagnosis between diseases essentially different, but that between the different and varying forms of each of those which we call by a generic name; and beyond this, we need a more exact power of what may be called analytic diagnosis; for there are few simple cases, and in those which are not simple we need to be able to discern all the components, and the proportions in which they are mingled or combined. Better treatment will follow better diagnosis, and better diagnosis will certainly follow a more exact pathology.

Let me illustrate this with an instance which is besides of some interest in the study of the variations of transmissible diseases and of the utility of museums. Questions are often asked as to changes which syphilis may, in course of time, have undergone; and, especially, whether internal organs were always, as they are now, liable to its attacks. It is hard to answer such questions on the evidence of any existing records; indeed, I might cite the whole history of syphilis as an instance of the insufficiency of records for the tracing of the natural history of diseases. But here is something suggesting what museums may do: a portion of muscle preserved by Hunter, and at least a century old, in which are morbid changes which may be safely referred to syphilitic gumma. Probably similar evidence may be found in other museums; and there are other facts significant of the existence long ago of these internal syphilitic diseases, as well as of the improved treatment following better diagnosis. Fifty years ago, at the beginning of my professional studies, it was the custom, as it long had been, to give mercury not only in all recognised syphilitic cases and in most acute inflammations, but in a large number of cases of which one could scarcely say more than that they were all chronic and all obscure. Especially there were many such cases of what were considered chronic inflammation of the eyes, and of the brain and spinal marrow, the liver, and the testicle. To all of these cases it was customary to give mercury till, as one said, "the mouth was touched," and thus some were cured, and some uncured, and some harmed. The cures were enough to keep the mercury in such good repute that it was given more and more generally; and then the disappointments, as they were called, became too many, and the mercury was blamed, and was almost disused for chronic inflammations. But, meantime, a more exact pathology, a pathology more exact both in its morbid anatomy and in its clinical studies, was discovering the previously unsuspected syphilitic diseases of internal organs; and with this better pathology there came a better diagnosis, and with the better diagnosis a more judicious use of mercury, and good reason to believe that the chronic and obscure cases which mercury used to cure were those of syphilis overlooked. The case is an exemplary one of the relations between the true pathology and the right treatment of diseases, exemplary not only for encouragement, but for method of study; for the study was both clinical and anatomical, in the living and in the dead, with records and with specimens. Such must be our study of all the cases which I have chosen to speak of—the cases in which diseases deviate from their usual type, or combine in various proportions, after the manner of hybrids and mongrels or new chemical compounds. But there are some rules in study which are especially applicable to these cases.

1. We should very carefully study all cases which are not according to an admitted type. We should study all exceptions to rules; never thinking of them as unmeaning or accidental. Especially, we should never use, in its popular, but wrong translation, the expression "exceptio probat regulam"; as if an exception to a rule could be evidence that the rule is right. If we use it, let this be in its real meaning; translating it, as surgeons should, that an exception proves a rule, tests it, searches it—as the Bible says we should "prove all things"—to its very boundary. In this true meaning the words may be an excellent motto for the study of all diseases that deviate from types.

2. We should look out for indications of the existence in the same person of two or more morbid conditions or dispositions such as may be derived from both parents or from several ancestors. For, as in plants and animals there are hybrids and mongrels, or, as in chemistry, many compounds and mixtures, so are there in diseases. We see them in the multifarious varieties of what we have to call rheumatic gout; in gout crossed with scrofula, and syphilis crossed or

mingled with scrofula or with gout. It is often not easy to discern some of these combinations among our cases, to know few things in practice more useful than to be able even in some instances, to adjust our treatment to the proportion of each disease in the compound. But we may be sure that there is much more to be learned in this direction, and it is best to believe that we rarely have to do with a simple and unmixed morbid constitution. There are worse habits in practice than that of commonly saying our case "It is all gout," and of another it is all scrofula, or all syphilis. We might as well say of any Englishman he is all Norman, or all Anglo-Saxon, or all Celt. We are indeed, sometimes see persons who appear to be as types, races unchanged in many centuries, but in practice we have a better study every man as, for better or worse, a compound of many ancestors.

3. We should have for all these cases a much more complete and exact study of all the personal causes of disease than is now usual. Of course this should include all that can be learned of each patient's history; though there are few parts of medical history more fallacious than this often is; and at the best will need, besides, the exactest study of the patient himself. Perhaps the brilliant success which has been achieved by the recent studies of disease-producing organisms or other materials acting on us from without, success not equalled in any other field of medical investigation, has made some think too little of those changes within ourselves which occur in such ordinary conditions of life that they may be called spontaneous. Yet these are the most important in the production of diseases, and therefore the most to be studied; just as in agriculture soils must be studied in their seeds. This is true even in respect of those diseases whose essential causes are most evidently external, even of those which are due to specific contagia; their germs or seeds may so speak, will not germinate in an unfit soil. Now there is not a day in which most of us do not inhale or come in contact with the germs of some frequent or common disease; but they do not germinate in us any more than the seeds of tropical flowers in our streets or in the soil in which the wind scatters them; we do not offer the right soil. And even among those in whom they do germinate the product varies according to the soil. And the soil of this soil, this living soil, is yet more necessary to be studied: diseases which come, in part or wholly, by inheritance, or it is in each as personal and distinct as any other disease of personal character, and the study of it must be minutely personal, with an exact analysis of every condition leading to disease. The aim of pathologists in this direction should be for knowledge like that of the keen family physician who, as he says, knows the constitution of every member of a family.

All this is equivalent to saying that these various diseases must be studied both in practice and in exact pathology. It is hopeless that either a practitioner or a student thinks lightly of pathology, or a pathologist who thinks lightly of observant practice, should do more in these questions than attain to that measure of partial knowledge which is often as deceptive as error. Each must be studied by the other. The living and the dead must be studied equally studied; and the dead must be studied by the observations, with accurate records, and especially in the museums.

I need not dwell on the value of good records, of descriptions, and good photographs, or other representations of diseases; but they never have been and probably never will be, enough. We need, with them, museums in which changes of structure may be preserved for repeated revising study and comparison. For instance, in the group of diseases of which I have been speaking, we ought to have in our museums specimens in which we study all the gradations of change of structure from the type, all the changes due to mingling of forms, all the changes of diseases, all hybrid forms. We need to be able to study all these things, as the naturalist or the comparative anatomist needs his specimens; not only for teaching, which is already known, but for continued re-examination and addition to his own knowledge.

And for complete study we must have large museums showing the coarse naked-eye characters of the gross structures. I am sure no one will think me likely to depreciate the microscope; it has added, and will continue to add, more than can be told to our knowledge; but it is not diminished the value of other evidence; and is

gical anatomy, as in all our sciences, there are many instances in which the naked eye sees facts with more accuracy than the microscopic one can.

This is, especially, true in the case of morbid structures resulting from nearly allied diseases, and, therefore, especially true for those of which I wish to urge the study. Morbid structures as in species the nearer the alliance the less are the differences to be found in minute structures, and the more must we depend for distinctions on the study of visible shapes, and sizes, and constructions. I suppose that we could not with the microscope distinguish the human skeleton from that of the monkey; certainly, we could not distinguish one skull from another in all those varieties of cranial form which are collected in our museum. And it is in many instances of morbid bone formation. I doubt whether microscopic examination could detect characteristic differences in each of this group of specimens. With the naked eye it is sure that this is a syphilitic node on a tibia, and this a growth beneath a chronic ulcer over the shin, and this a pedicled exostosis, or ossified cartilaginous outgrowth from the shaft of a long bone, and this an instance of osteo-arthritis, and this a portion of the skeleton of an osteo-sarcoma or osteoid cancer.

Moreover, it is to be observed that in morbid structures, as in those that are natural, in the same proportion as the aggregated elements of embryonic structures acquire their complete and final form, so do the bodies composed of them acquire distinctive shapes and methods of construction plain to the unaided senses. The ova of many species may seem alike both in outer shape and in their component elemental structures. But in proportion as these structures are differentiated, and developed into their higher and biding forms, as into nerve fibre, and muscular fibre, and so rest, so the larger characters of even the nearly allied species—the characters of shape, and size, and appropriate construction of the whole body, and of each part of it—become more and more different; and these constitute the real distinctive characters of each species.

And so it is in morbid products. The acquirement of distinctive shapes and methods of construction coincides with the development of elemental forms. For example, in these sarcomata are only the lowest elemental structures, round cells, spindle cells, and shapeless plasma; and the masses thus combined are shapeless, featureless, decisive by negation. But in these fatty and fibrous and cartilaginous and bony tumours, in which the elemental structures have advanced to higher forms, the masses which they everally compose are almost as characteristic and distinct in visible shape and construction as are the several normal organs of the body.

In every case, then, both the largest and the smallest characters should be studied. The naked eye can discern one set of facts, the aided eye another; both are essential to complete knowledge; no one should be content with either, or neither is alone sufficient. So we must have large specimens as well as small ones, and certainly large ones for the study of the gradual variations of diseases as they deviate from typical forms, and become variously mingled.

And now, as I come near to my term of time, let me, as is customary in certain other places, conclude with an earnest appeal to your liberality. We want liberal contributions, not of money, but of specimens to our museum. We want specimens of many kinds; of course we want whatever is rare, but not these alone; we want some to complete our series of typical specimens; and, to keep to the chief subject of my lecture, we want the opportunity of choosing among many of what are called "bad specimens." We are all too ready to collect what are called good specimens as being well-marked instances of the standard characters of diseases, and to put aside as "bad" those which deviate from those characters, just as, clinically, we speak of good and bad cases of a disease. Of course, good specimens, typical specimens, must be at hand for the teaching of pupils who have to study illustrations of the accepted descriptions of diseases; but it is among bad specimens, even as it may be among exceptional cases, that those who are past pupillage, though they have not ceased to be students, may study the variations of disease. I ask the more boldly for contributions to the pathological collection because of its present satisfactory condition and the activity of work in it. You will soon see it in the repaired and renovated building. Looking at the number and value of the specimens and the wide range of pathology which they illustrate; looking at

the interest of the history of our science which is told in many of them; at the memorials of Hunter and Matthew Baillie, of Astley Cooper, Liston, Howship, Lawrence, Hammick, Fergusson, Hilton and many more; looking forward to what the museum will tell of the researches and skill of those who are still with us, and among whose names I venture to feel sure, Mr. President, that none will take precedence of your own, while men study the specimens with which your skill and just audacity in operating have enriched the series of diseases of the ovaries and uterus: looking at all these things, and then at the perfect order and condition in which the specimens are preserved, I feel that the collection is one which all we members of the College may feel personal pride in calling our own, and should feel a personal duty to enrich. And its utility is being constantly more appreciated. I have been often made happy by the contrast which I have seen while working at the new edition of the catalogue. While I was writing the last edition, between thirty and forty years ago, scarcely a student ever entered the museum. Hour after hour I sat alone; I seemed to be working for no one but myself, or for nothing but the general propriety that a museum ought to have a catalogue, though no one might ever care to study with it. Now, and for some years past, a day rarely passes without many pupils and others being at work in every part of the museum.

All this is good; but much more is to be done. Our museum should be, even more than it is, the centre in which all pathologists may find help in searches after that which is not yet known; in such searches, for example, as may lead to a complete knowledge of the variations of diseases. For many years, even from the beginning, the anatomical and physiological departments of our museum have been not only a noble collection of specimens, but, through the renown and learning of its conservators, a great centre of teaching. Scientific men, especially comparative anatomists and anthropologists, have known that here, if anywhere, they could find whatever help a museum and a master in those sciences could give. A fortnight ago the President of the Royal Society, presenting one of the royal medals to Prof. Flower, said: "Professor Flower has been for more than twenty years conservator of the museum of the Royal College of Surgeons; and it is very largely due to his incessant and well-directed labours that the museum at present contains the most complete, the best ordered, and the most accessible collection of materials for the study of vertebrate structures extant."

It is not for me to praise the pathological collection with similar words. But great as may have been its utility hitherto, we may be confident that it will henceforth be more useful than ever. In the vast increase of the biological sciences it became impossible that one man should be nearly complete in the knowledge of both natural and pathological anatomy. I say impossible. I believe there is not such a one living; if there could have been one it might have been Mr. Flower. Now, we may hope that labours as "incessant and well-directed" as his will be devoted especially to the pathological collection.

It is known to many of you that Sir Erasmus Wilson, in his usual liberality, gave the College £5000, of which the interest should be spent in the promotion of pathology; and he agreed that this would best be done by helping to the appointment of a curator of the pathological department of the museum; and we have an admirable one. Mr. Eve is a worthy colleague and helper of Mr. Flower, excellent like him not only in knowledge, but in that which is even more rare, the love of museums, and of all that belongs to their maintenance and illustration, even to the making of catalogues. In all these good qualities he has distinguished himself at St. Bartholomew's. I believe that we may rely on him for making so good use of the museum, and of all that can be brought to it, that the College shall be the chief centre for the study of pathology, even to the furthest point at which it can be studied in specimens of diseased structure. I beg your help that he may be so; and if I shall have helped to-day to this good result, the first Bradshawe lecture in our College will have well fulfilled the purpose of its founder.

A FIRE, fortunately unattended with loss of life, broke out a few days ago in the Rochefort Hospital, France. A portion of the left wing and much valuable property were destroyed.

Delivered at Charing Cross Hospital,

By T. HENRY GREEN, M.D., F.R.C.P.,

PHYSICIAN TO THE HOSPITAL,  
SENIOR ASSISTANT-PHYSICIAN TO THE HOSPITAL FOR CONSUMPTION  
AND DISEASES OF THE CHEST, BROMPTON.

### LECTURE III.

*Question of distinct varieties of Phthisis. — Clinical varieties due to differences in the pathological tendencies of the pulmonary consolidation. — Consideration of the lung lesion, and of the symptoms which accompany it. — The characters of the pulmonary consolidation; the extent and distribution of the consolidation; the quiescent or progressive nature of the consolidation; the predominating characters of the consolidation, and the physical signs which accompany them. — Secondary changes. — Resolution. — How far is the complete cure of phthisis possible? — Difference between resolution and arrest of disease. — Those cases in which resolution can take place. — Softening and excavation. — Fibroid overgrowth and bronchial dilatation.*

GENTLEMEN,—In our consideration of the diagnosis of Phthisis, we have thus far been concerned only with the simple recognition of the existence of this disease. This, as we have seen, is for the most part easy, and only in exceptional cases presents real difficulty. The simple recognition of phthisis, however, is but a preliminary and comparatively small part of our inquiry. In a disease which presents such manifold clinical features—some cases terminating fatally in a few weeks, whilst others, which perhaps at the first appear much more grave, last for years, the patient enjoying comparative health—some attempt must be made at the onset to form an opinion as to its probable course. Here we are met by the question:—"Are there distinct varieties of phthisis which we can so clinically distinguish as to be able to say in any given case that the disease will be accompanied by certain symptoms, exhibit certain pathological tendencies, and run a certain course? To this, I think, we must answer, No; the answer which our previous consideration of the pathology of the disease will have led you to anticipate. Our opinion as to the probable course of phthisis must be based upon a careful consideration of each individual case; and we are not likely, I believe, to be aided in our prognosis by attempts to make artificial divisions of the disease.

The clinical varieties of phthisis depend for the most part upon the pathological tendencies of the pulmonary consolidation, and having ascertained the existence of the disease, we must endeavour to form an opinion as to what these tendencies are. In order to do this, we consider both the lung lesion and the symptoms which accompany it.

#### THE LUNG LESION.

A careful consideration of the pulmonary lesion as it is revealed to us by a physical examination of the chest will naturally be made in all cases. We must take into account here:—(1) The characters of the consolidation; (2) the extent and distribution of the consolidation; and (3) the quiescent or progressive nature of the consolidation.

I. *The Characters of the Pulmonary Consolidation.*—The characters of the pulmonary consolidation must be considered with reference to the kind of change which predominates, and to the secondary alterations—resolution, softening, and fibroid induration, which the consolidation undergoes. Here I must ask you to bear in mind some of the histological facts which engaged our attention in a preceding lecture. Remember, firstly, that phthisical consolidation of the lung consists of three kinds of change, which tend to be associated, although in very different degrees; secondly, that which of these changes predominates and the secondary alterations which the consolidation undergoes, depend mainly upon the intensity and duration of the phthisical process; and, thirdly, that there is no necessary

relation between intensity and tendency to spread, some of the most intense processes being often the most localised, and *vice versa*.

The kind of change which predominates can usually be only approximately determined, inasmuch as intra- and extra-alveolar changes are, as we have already stated, so constantly associated. At the same time the consolidation is in many cases so markedly either intra- or extra-alveolar, that we are able to speak with tolerable certainty on this head; and as the outcome of the disease in the two cases is often very different, this differential diagnosis is important.

Our opinion as to the predominating characters of the pulmonary consolidation will be based upon the abnormal physical signs, and inasmuch as these characters are so largely influenced by the intensity and persistence of the phthisical process, these signs will at the same time be valuable indications of the mode of onset and duration of the disease. The diagnostic value of physical signs in this twofold direction I have endeavoured to tabulate for your guidance. Understand, however, that owing to the association of the several changes, the following statements must be accepted as only approximately true.

#### A. CONSOLIDATION INTRA-ALVEOLAR.

##### Physical Signs.

1. Dulness without retraction, the dulness varying according to the extent and situation of the consolidation.
2. Respiration impaired, deficient, slightly harsh or bronchial in character, according to the degree of the consolidation.
3. Dry or moist small crepitant râles, heard especially at the end of deep inspiration, and often only after cough.

##### Clinical History.

As contrasted with *B* and *C*, onset of disease often less insidious, and lung symptoms more pronounced. Physical signs of intra-alveolar consolidation without those of the retraction met with in *B* and *C* always indicate that the disease is in an early stage.

#### B. CONSOLIDATION INVOLVING MAINLY ALVEOLAR WALLS.

##### Physical Signs.

1. Dulness usually less pronounced than in *A*. Often slight retraction in the earliest stages, most commonly indicated by some diminution in the area of supra-clavicular resonance.
2. Respiration slightly deficient, but less so than in *A*; harsh and slightly bronchial in character.
3. Dry and moist small crepitant râles often entirely absent; and if present, obscure, scanty, and only occasionally audible.

##### Clinical History.

As contrasted with *A* the onset of the disease is usually more gradual, and the lung symptoms less pronounced. There is often more marked failure of the general health. The progressive tendency of the consolidation is greater, and the prognosis generally less favourable.

#### C. CONSOLIDATION CONSISTING LARGELY OF INTER-LOBULAR CONNECTIVE TISSUE.

##### Physical Signs.

1. Dulness with marked retraction. Percussion note often tubular in quality. Retraction frequently sufficient to cause encroachment of opposite lung across the middle line anteriorly, displacement of heart, &c. (These signs present without the existence of excavation.)
2. Respiration markedly bronchial, or even cavernous.
3. Dry and moist crepitant râles absent, unless, as is often the case, associated with alveolar changes.

##### Clinical History.

Fibroid overgrowth is in the great majority of cases secondary to *A* and *B*, and its existence indicates that the disease is in a more or less advanced stage.

The secondary changes which take place in the pulmonary consolidation—resolution, softening with excavation, and fibroid overgrowth—are obviously of the greatest importance as influencing the clinical history of the disease. In most cases of phthisis all these three changes take place, although in very different degrees; some portions of the consolidation undergoing complete resolution, whilst in others the lung

ed, and in others again the softening process by a fibroid growth. These several changes or separately, and the physical signs which we may again indicate in a tabular form.

**Resolution.**—Here we are met by the question:—How far resolution of the pulmonary consolidation, in complete cure of phthisis, possible? That in the consolidation undergoes resolution doubt; but unfortunately the resolution is so much residual lesion is left, that the disease is not materially influenced by it. At the same time, the most of those who have had much experience of phthisis will, I believe, admit that cases are occasionally met with in which resolution is practically complete, the lung being left almost as little damaged as after an attack of acute pneumonia. Understand that we are speaking now of resolution of the consolidation, and not of arrest of the phthisical process. These two modes of favourable termination it is important to distinguish.

**Arrest of the phthisical process with residual lesions is sufficiently common;** but such residual lesions, consisting usually of some fibrosis with slight bronchial dilatation or encapsuled caseous products, although they may remain permanently quiescent, constitute elements of danger which do not obtain where the resolution is more complete. In considering the question of resolution, the predominating characters of the pulmonary consolidation become of the utmost importance, inasmuch as of the threefold lesion of phthisis it is the intra-alveolar products which are alone capable of absorption, and it is therefore those cases of phthisis only in which the consolidation is mainly intra-alveolar that resolution is possible. Intra-alveolar changes are, as we have seen, often most prominent in those cases of phthisis the onset of which is the least insidious, those cases in which the consolidation is the most rapidly induced, and the lung symptoms are the most pronounced; and it is just these cases which often have the most favourable termination, the consolidation disappearing with little or no residual lesion. Such cases, however, bear in mind, can only terminate in resolution, provided (1) the intensity of the phthisical process is not too great, and (2) the duration of the process is not too long. Any marked intensity or prolongation of the process must invariably lead, as our previous considerations will have led you to understand, to more or less cellular infiltration of the alveolar walls, and consequent destruction of lung tissue. In speaking of resolution, you will remember that though in some few cases the lung appears to be completely restored, much more commonly resolution is so far incomplete that some slight shrinking and alveolar thickening are left.

The physical signs met with in those cases in which the consolidation is invariably intra-alveolar we have already indicated. It remains to consider here those signs which in a case of intra-alveolar consolidation accompany the process of resolution. These signs may be thus tabulated:—

#### INTRA-ALVEOLAR CONSOLIDATION—RESOLUTION.

1. Gradual disappearance of dry and moist small crepitant râles. Diminution in the percussion dulness, and in the deficiency of the respiration.

2. In some cases the above-named signs of improvement are soon followed by the disappearance of all abnormal physical signs; but more commonly, owing to slight shrinking and induration of the lung, there remains slight diminution in the area of supra-clavicular resonance, with perhaps slight deficiency and harshness of inspiration. These signs may also ultimately disappear owing to the development of some compensatory emphysema.

**Softening and Excavation.**—This is the most characteristic secondary change of phthisis, constituting the so-called second and third stages of the disease. It is hardly necessary for me here to remind you that these stages of phthisis have reference only to the condition of the pulmonary consolidation, and have little if any prognostic import, the life of a patient in the third being often infinitely more valuable than that of one in the first stage of the disease. The process of softening is most marked in those cases in which the lesion is mainly intra-alveolar, those cases in which, as we have seen, the consolidation is often the most rapidly induced. The physical sign which is the most characteristic of this process is that liquid, high-pitched, crepitant râle known as moist crackling. Where the consolidation is more slowly developed, and the changes are rather extra- than intra-alveolar, the process of softening is

more gradual and consists in a slow molecular disintegration. In such cases moist crackling may be absent, and there may be nothing to indicate the destructive process until signs of excavation declare themselves. It is during this period that elastic tissue may be discovered in the sputa, and its presence is valuable corroborative evidence of the destruction of the lung. The outcome of the softening process is cavity formation. This is effected by a communication being established between the softened portions and a bronchus through which some of the softened matters are expelled. In most cases the softening commences at several separate centres, which increase and gradually coalesce. The physical signs of excavation now become apparent, provided the cavity be of sufficient dimensions. It is probable that a cavity must be at least half an inch in diameter to give diagnostic physical signs. These signs will vary considerably according to the size and situation of the cavity, the amount of secretion it contains, and the size of the bronchus with which it communicates. They comprise gurgling râle, cavernous respiration, pectoriloquy, &c. A cavity once formed may continue to extend, or the destructive process may become arrested. In the latter case the cavity may gradually dry up and contract, or it may continue to secrete purulent liquid. It may also become the seat of secondary ulceration. These several changes give to the disease important clinical features which must engage our attention on a future occasion.

**Fibroid Overgrowth.**—This we have already described as invariably present in all cases of phthisis the duration of which is sufficiently prolonged, and in these it may constitute the predominating constituent of the pulmonary consolidation. As it appears, however, to be always preceded by other inflammatory lesions, we must allude to it here amongst the secondary changes. The physical signs which accompany it we have just considered. They are in the main those indicating consolidation with diminution in the size of the lung, and more or less bronchial dilatation. This dilatation of the bronchi, a most important result of pulmonary fibrosis, has not yet engaged our attention. It occurs to a greater or less extent in all fibroid lungs, and from the great liability of the dilated bronchi to catarrhal processes, and the difficulty of expelling the secretion from the enlarged and rigid tubes, its existence gives marked features to the disease. The importance of fibrosis in encapsulating and limiting the more localised phthisical lesions we shall have to consider when speaking of the quiescent and progressive character of the consolidation.

#### THREE CASES OF DEPRESSED FRACTURE OF THE SKULL, IN WHICH THE TREPHINE WAS SUCCESSFULLY APPLIED.

BY H. BLANC, M.D.,  
PROFESSOR OF CLINICAL SURGERY, MEDICAL COLLEGE, BOMBAY.

**CASE 1. Depressed Fracture of the Skull; Slight Compression of the Brain; Localised Inflammation of the Brain and its Membranes; Progressive Paralysis of the Face; Application of the Trephine; Recovery.**—Appa Nartha, a Syce, aged thirty, a Hindoo of the Maratha caste, was admitted into the clinical surgical wards of the Jajmsetjee Jejeebhoy Hospital on December 15th, 1880, suffering from a fracture of the skull. It appears that the horse Appa was leading suddenly reared and struck him on the forehead with its hoof. The patient fell to the ground insensible, and remained in that condition for a short time. Considerable hæmorrhage is said to have taken place. After a while, when he had recovered consciousness, he was unable to walk, even when assisted; he felt confused, his sight was dim, he did not recognise his friends for a time, and he had entirely forgotten how the accident occurred.

On admission, two hours after the accident, his condition was as follows. The face was pale and anxious; the pupils slightly dilated; the skin was hot and dry; the pulse slow (60), regular; he was conscious, and answered questions rationally; he complained only of feeling giddy and great weakness. On the forehead there was a contused wound, beginning just above the left frontal eminence, and running obliquely downwards

towards the right side. The bone was exposed and fractured; a depressed fragment being distinctly felt with the probe; the parts around were swollen and painful; the right upper eyelid was ecchymosed. He progressed favourably for the following six days, but on the morning of the seventh day (Dec. 22nd) he complained for the first time of pain in the head. His sleep during the preceding night had been disturbed. There was some dyspnoea present, with increased frequency of respiration, and at the base of the right lung some dullness on percussion and increased vocal resonance were detected. Temperature 100°; pulse 60. The wound was dry-looking and of a dusky colour. The following day he was better. The dullness at the base of the right lung had given way to treatment.—Dec. 26th: The pain in the head has been increasing gradually, and is now very severe; for the first time this morning some ptosis of the left eyelid is noticed. The breathing is shallow and hurried, although no physical sign of disease of the lung can be detected. Temperature normal; pulse 60, equal, somewhat compressible. On Dec. 27th the attendant reported that the patient had passed a very bad night. The left angle of the mouth was depressed, and there was marked flattening of the whole of left side of the face. The wound on the forehead looked unhealthy, discharging sanious pus. Temperature normal; pulse 60. The progress of the case being decidedly unfavourable and localised, inflammation having been diagnosed, I decided on applying the trephine and removing the depressed fragments. The patient being placed under chloroform, a crucial incision was made, and the flaps, which included the pericranium, were dissected back. A depressed fracture was then found situated at the line of union of the frontal bones, but involving more the right bone. The fracture measured half an inch in breadth and one inch in length. All bleeding having ceased, and the parts having been thoroughly cleaned, a small trephine was applied, resting partly on the healthy and partly on the fractured bone. A portion of the bone having been thus removed, the depressed fracture was found to consist of several fragments which were easily removed, but around the fracture several detached fragments were also found, these latter belonging to the inner table of the bone, and some of them had penetrated through the dura mater into the brain. All of these were removed. A careful examination was then made to ascertain that no pieces had been left, when a little above the upper angle of the fracture a large fragment about half an inch in length was detected penetrating into the longitudinal sinus. It was very carefully removed; nevertheless a terrible gush of blood followed. I at once introduced my index finger into the wound and placed it on the spot whence the blood was flowing, and did not remove it until the hæmorrhage had entirely ceased. The parts were then cleaned and the flaps brought together by sutures, a fine drainage-tube having been previously introduced. The wound was dressed antiseptically. On the following morning (Dec. 28th) a great improvement was found to have taken place in the case. The temperature was normal; the pulse 72, of fair volume and regular; the respiration regular, 22; the ptosis of the left eye was much less marked, and the paralysis of the face had disappeared. He appeared cheerful, and answered questions rationally; he had quite lost the pain in his head.

For a while he progressed very favourably, but on Jan. 9th, 1881, he complained of difficulty in swallowing; there was some rigidity in the muscles of the jaw and neck; he vomited several times during the day; his tongue was foul at the base and red at the tip; his look vacant and stupid, and he did not answer questions readily; there was some return of ptosis of the left eyelid. He complained of no pain, and the wound looked healthy. On the 11th his condition was somewhat worse, and during the night he had an epileptiform convulsion. On the 12th he appeared somewhat better at the morning visit, but in the afternoon his condition became very critical; he was comatose; breathing hurried; pulse thready, 118; temperature 102.4°. During the following day (January 13th) he seemed several times on the point of death. Incontinence of fæces and of urine; in deep coma, from which he could hardly be roused; the pulse at times imperceptible. On the 14th some slight improvement, but still very bad. On the 15th the improvement was more marked; he was again conscious; pupils still dilated, but less so; he could open his mouth better. Vomiting, which had been more or less persistent since the 9th inst., now ceased. Pulse 108, more full and regular; temperature 98.8°. The wound on the forehead, which had

nearly healed, was found to be raised and pulsating, and the dressing was covered with a considerable amount of healthy pus. On the 20th he had made great progress towards recovery; the ptosis of the left eyelid had again disappeared. Temperature normal; pulse 86. He was quite conscious; answered questions rationally, slept at night, and asked for more food. Day by day he gradually improved, gained strength and flesh. His nights were good, and he seemed to enjoy his food; he was in good spirits and cheerful. A small pulsating tumour that had formed at the seat of the injury gradually increased in size, distending and partially separating the recently united skin flaps.

On the 1st of March the hernia cerebri was smaller, the granulation on its surface had healed, but it was still the seat of marked pulsations. He was soon able to take exercise about the wards and verandahs. By the 20th of March the wound on the forehead had partially cicatrised, and pulsations were no longer visible. He was discharged perfectly well on the 1st of April.

Some weeks ago I made inquiries regarding him, as I wanted to see him. His brother called at the hospital and told me that our patient had gone to his village on leaving the hospital, where he was still residing in the enjoyment of good health. He complains only of not being able to carry burdens on his head as he had formerly been able to do.

**CASE 2. Depressed Fracture of the Skull; Compression of the Brain on its Convex Surface; Partial Paralysis and Contractions; Application of the Trephine; Recovery.**—Pourbai Souther, a Mussulman woman of the Khoja caste, aged twenty-three, was admitted into the clinical and surgical wards of the Jamsetjee Jejeebhoy Hospital on Dec. 15th, 1881, suffering from a depressed fracture of the skull, caused by a box falling on her head from the third storey of a house as she was walking in the street. She was taken to the hospital immediately after the accident. On admission her condition was the following:—There was a lacerated wound, some two inches in length, situated on the right parietal bone, near its centre, and extending backwards towards the occipital bone. The bone was fractured in the same direction as the external wound. The pupils were dilated, the left more than the right. Pulse 102; respiration 24; temperature 98°. There was no loss of consciousness, and no paralysis; but she was somewhat hysterical, and still under the influence of shock.

On the following day there was slight reaction. The temperature rose to 101.4°, and the pulse to 110. She was somewhat restless and delirious. There was retention of urine and constipation. On the 18th her condition was much the same, but some paralysis of the left lower extremity was noticed. On the 20th she experienced a rather severe epileptiform convulsion. On the 21st she was somewhat delirious, and during the night had another severe epileptiform fit. When conscious she complained of a severe pain in the head. There was increased paralysis of the left lower extremity, and some loss of power in the left arm. On Jan. 11th her condition was still worse, the loss of power in the lower extremity was more marked, and for the first time attended by muscular contraction. The arm was quite powerless. During the night she was very excited, but at the morning visit she was drowsy and listless.

In presence of the progressive and increasing paralysis of the left arm and leg, to which contraction was now superadded, the application of a trephine to the fractured bone was decided upon, and the patient being placed under the influence of chloroform, a crucial incision was made over the scalp wound. The flaps having been dissected, a small trephine was applied partly on the healthy and partly on the fractured bone, and on removing the circle of trephined bone a large fragment was found to have been pushed and firmly wedged beneath the sound parietal bone. This piece was removed by forceps. The dura mater at the spot appeared rough and congested, but it was not lacerated. The wound was united by suture, a fine drainage-tube being introduced. The wound was dressed antiseptically.

Jan. 12th.—The patient passed a good night. Moderate reaction present; pulse 104, temperature 101°. All symptoms of paralysis have entirely disappeared; she is able to empty her bladder without assistance. During the next forty-eight hours moderate reaction persisted, and she suffered also from chloroform vomiting; otherwise progress was most favourable. On the 18th the report of the case is the following: Temperature normal, pulse 76, of good volume; bowels regular, sleeps well, and asks for food. She can move her arm and leg freely. The wound looks very

hy, and is uniting. The further progress of the case steady and good. She gradually regained her strength, she was soon able to walk about the wards and in the pens. When she left, on Feb. 2nd, the wound on the head was firmly united, and she was altogether in perfect health.

**CASE 3. Depressed Fracture of the Skull; Concussion of the Brain; Contusion and Laceration of the Meninges; Meningitis; Application of the Trephine; Recovery.**—**ETABA**, a Hindoo girl aged twelve, was admitted to the clinical surgical wards of the Jamsetjee Jejeebhoy Hospital on March 31st, 1882, suffering from fracture of the skull and other contused wounds, the result of a fall. Of somewhat weak intellect, and subject to epileptic fits, she was standing on the summit of a steep hillock (Belvidere, Mazagon) when she fell to the ground, seized with an epileptic fit. Under the influence of the fit she rolled along steep and rough incline of the hillock, some sixty feet. She was picked up insensible and at once carried to the hospital. On admission her condition was as follows:—There was a lacerated wound situated above the left eyebrow, and which extends directly upwards and backwards for about one and a half; the bone is exposed, fractured, and depressed at the centre of the fracture. Some deep lacerated contused wounds are found in the following positions:—over the left malar bone, one some three inches in length over the left side of the thorax, another over the hip-joint, and many smaller abrasions and contusions seen on different parts of the body. Both ankles are much swollen and tense. She is still unconscious; pulse small; respiration shallow, 80. She now and then starts and moans, and frequently carries her hand to the head on her head.—April 1st: She is drowsy, but can be roused somewhat. She is unable to answer questions put to her. Bladder distended; ten ounces of urine withdrawn by catheter; specific gravity 1016. Towards evening the temperature, which had been normal until then, began to rise and acute delirium set in. Pulse 114; respiration 32.

April 2nd.—She passed a very bad night; great restlessness and delirium. This morning temperature 104°; pulse 114; respiration 32. All day she remained in the same condition, the pulse losing strength and becoming very rapid. The prognosis being very unfavourable, an attempt to relieve her condition by applying the trephine was decided upon, and at 6 P.M. she was placed under the influence of chloroform. A crucial incision having been made at the seat of the fracture and the flaps dissected back, a small trephine was applied over the centre of the fracture. This having been removed, a few loose small fragments were found lying on the dura mater. One sharp-pointed fragment had lacerated the membranes and wounded the brain. From around and beneath the fracture some clots of blood were removed. The dura mater at the seat of the injury was much injected and of a violet colour. A slight oozing allowed the removal of the penetrating fragment. The flaps were brought together by wire sutures, a small drainage-tube being introduced. The wound was dressed antiseptically.—April 3rd: Still delirious, but less violent than the day before; urine withdrawn by catheter. Temperature 102°; pulse 104. She became more excited towards evening, and the temperature rose slightly.—4th: Passed a pretty fair night, neither noisy nor restless; she is still unconscious; passes urine in bed. The right ankle is much swollen and painful. Temperature 103°; pulse 100; respiration 24. Towards evening the temperature fell to 100°. The following days she remained in about the same condition, at times quiet, at times noisy and violent. She took nourishment badly. An abscess formed near the right ankle-joint, and after it had been opened (April 9th) the temperature fell to normal.—17th: Passed a fair night; answers questions when pressed to do so; generally lies quiet or moans; no longer passes water in bed, but calls for the nurse; takes nourishment fairly well; the wound on the head discharges slightly. Temperature 99°. For a while she again became somewhat violent and restless at night; several abscesses formed at the seat of the contusions, and much of the uneasiness she experienced about that time was doubtless due to these inflammatory abscesses. In the beginning of May the improvement in her condition was more marked; she understood what was said to her, but was unwilling to answer, and when she did so it was in a cross, angry tone, as if annoyed at being disturbed; she now slept well at night, her bowels were regular, she took her food better, her temperature was generally

normal; the pulse averaged about 80, and was weak and compressible; the wound on the forehead was nearly healed, a few drops of sero-purulent discharge alone soiling the dressing; all the other abscesses were completely healed.

May 14th.—She is in a fair way towards recovery; is able to sit up in bed, takes her food well, is gaining a little strength; she is sulky and cross generally, and is still unwilling to speak when questioned. According to her parents she is intellectually very much the same as she was previous to the accident. Discharged at her parents' request.

The first case is one of a depressed fracture of the frontal bone, attended by slight concussion of the brain. On the seventh day after the injury the individual, who until then was doing well, was suddenly seized with progressive facial paralysis, dyspnoea, &c. These symptoms (taking into consideration the date of their appearance) indicated localised inflammation of the brain due to the presence of depressed and penetrating fragments of bone acting as a foreign body. That this was the case was amply proved by the result of the operation. The relapse which followed a few days afterwards was due to the contused brain undergoing suppuration, and owing to a free exit having been made by the trephine, the abscess was evacuated externally, and rapid recovery ensued.

In the second case we have to deal with a well-marked instance of functional disturbance of the brain. There was compression of the brain on its convex surface (a piece of bone being firmly wedged in), but unaccompanied by symptoms of compression. The paralysis and contraction which afterwards developed were due to disturbed cerebral circulation, and to localised congestion, rather than to inflammation. This is implied by the rapid improvement that followed the operation.

In the third case there was severe concussion of the brain, with laceration and contusion of the meninges. The very rapid and unfavourable progress of the case made the prognosis a most serious one. Nevertheless, after the penetrating fragments had been removed the further progress of the cerebral inflammation was considerably lessened.

Apart from their diagnostic value, I think that these cases will assist in rehabilitating the operation of trephining the skull in appropriate cases. These three individuals would, in all probability, have succumbed to cerebral inflammation had not operative surgery interfered on their behalf.

Bombay.

#### NOTES OF

### THREE ABDOMINAL CASES OF INTEREST.

By J. A. CAMPBELL, M.D., F.R.S.E.,

MEDICAL SUPERINTENDENT, GARLANDS ASYLUM, CARLISLE.

**CASE 1.**—**M. C.**, a female aged at death fifty-four years, had been admitted into the Carlisle Asylum in the year 1862, and at that time was described as labouring under mania and being in weak bodily health. My knowledge of her included the latter fifteen of the twenty years she lived in this asylum. She laboured under many delusions, talked much to herself, enjoyed good bodily health until shortly before her death, and was industrious and useful. From the many entries in her case I find that little or no ostensible change in mental or bodily state was noticed up to January, 1879, when she had an attack of vertigo, and for some days felt out of sorts. She, however, continued in her usual bodily state during 1880. In the latter half of 1881 she became thinner, her skin became yellower than it used to be. On more than one occasion she was examined, but no active disease or indication of organic disease could be found. It was noted, however, that she had a cancerous look.

On Jan. 22nd, 1882, the patient complained of feeling ill, but owing to her incoherent expressions it was impossible to get her to say more than that she felt ill. She vomited, her tongue was moist and clean, her temperature normal; pulse 78, small. An examination of the chest showed a normal condition of the thoracic viscera, and nothing abnormal could be detected as regards the abdominal organs; as there seemed a tendency to constipation of the bowels and

enema of tepid water was administered, which produced two alvine evacuations. On the 23rd there was little change in the patient; she took food, but looked ill. On the 24th the morning temperature was 99°; pulse 96. She looked worse. Abdomen tympanitic and tender to the touch; no fluid in the abdominal cavity. Ordered half a grain of opium in a pill each hour. In the evening she complained of acute pain, referable to the region of the stomach, was sick, and retched much. A hot fomentation was applied and retained for some hours over the abdomen, but as relief from pain was not at once caused by hot application a subcutaneous injection of morphia was administered above the region of the stomach. Cessation both of pain and sickness immediately followed this treatment. Pain and sickness, however, recurred later in the day, but disappeared on a repetition of the injection. On the 25th the morning temperature was 98°; pulse 96. Tongue furred and dry, pulse small, tenderness over abdomen, but nothing abnormal could otherwise be discovered. Decubitus on the back, with a tendency to draw up the legs. On the 26th the morning temperature was 97°; pulse 74. Tongue furred; during the night the bowels had been three times moved, fæces normal in colour but unformed. Abdomen tympanitic, tense, and tender. On the 27th the morning temperature was 97°; pulse 80. Was weaker and looked worse. Abdomen less tympanitic and tense; has taken a fair amount of liquid food. On the 28th she was worse, pulse more feeble, skin cold. On the 29th she became worse and died.

*Autopsy, forty-two hours after death.*—The body was thin, and the skin tinged yellow. The brain was examined, but no abnormalities detectable by the naked eye were observed. Chest: The lungs were slightly adherent to the parietes by old adhesions; the bases of the lungs posteriorly were passively congested, and the structure of the lungs, on section, was normal. Heart: Muscular substance fatty; valves competent. Abdomen: The liver was light-coloured, friable, and fatty. Gall-bladder contained twelve small dark-coloured calculi (a large biliary calculus was subsequently found in the small intestine). The spleen was dark and soft, and the kidneys congested; otherwise normal. There was evidence of peritonitis of the outer coat of the intestine, more especially of the large intestine. There was no fluid in the abdominal cavity, and the peritoneum lining the abdominal parietes was in a normal state. The intestine was taken out and examined; nothing unusual, except the already mentioned biliary calculus, was noted about the small intestine; but the large intestine, down to the sigmoid flexure, was much distended, and contained flatus. There was a ring of hard cancer about an inch above the sigmoid flexure, which formed a constriction, only admitting one finger; and about three inches above this there was an ulcer, about the size of a penny, with irregular and indurated edges. There were no other abnormalities in the large intestine.

CASE 2.—J. M.—, a female, aged sixty years at death, was admitted in June, 1871, labouring under melancholia, and in very weak health; pale, thin, cachectic-looking, and to all appearances very aged for years. I always suspected internal cancer from her appearance. All forms of treatment to improve her bodily health and to increase her weight (which on admission was 106 lb., height 5 ft. 2 in., and which diminished to 88 lb. within the first ten months), proved unavailing. She resented the slightest interference, never spoke, but bit, struck, kicked, or scratched if any attempt at examination was made. She had a habit of rubbing her hands, and did so so continuously that an abscess formed connected with the first finger of the right hand, and also another abscess connected with the fourth finger of the left hand. In spite of treatment disease of the cartilage and bone set in in both fingers, and they had to be removed. Healing took place extremely slowly, in fact for a long time little or no change seemed to take place in the severed tissues. On March 1st, 1882, it was noted that she was becoming gradually thinner and weaker, and on more than one occasion, but at considerable intervals previous to this date, she had had a loose stool followed by great pallor, faintness, and coldness. She resisted all attempts at examination with extreme viciousness. On several occasions she has been examined while being forcibly held. The result of these necessarily imperfect examinations may shortly be stated—viz., that percussion over the chest was clear, that some mucous râles were heard over both lungs, that the heart sounds were feeble but distinct, and that nothing abnormal was detected by percussion or touch; as regards

abdomen, her temperature was subnormal, her bowels were moved regularly, she took a fair amount of food, but she became gradually paler, thinner, more cachectic-looking if possible, and died on March 7th, 1882.

*Autopsy, forty-nine hours after death.*—The body was thin, and free from marks of injury. The brain was examined, but no marked lesions were noticed, and it is, therefore, unnecessary to enter into a detailed account of the appearances. The left lung was closely adherent by old adhesions to parietes, especially at apex; its upper lobe was congested, both lungs contained some deposit of grey tubercle at apex. The pericardium contained two ounces of fluid; the heart was yellowish in colour, its muscular substance was fatty, its valves competent. Liver light coloured and friable. Spleen and kidneys normal. Stomach and intestines removed and examined; both were found in a normal state, with the following exception. At the caput cæcum there was a thickening and appearance of tumour, as if the caput cæcum were crammed full of contents of a firm nature; on removing and laying it open the whole of the inner surface of the caput cæcum was found covered over with irregular masses of hard cancer, but the cavity of the viscus was patent, the external surface presenting a smooth and normal appearance.

CASE 3.—E. H.—, aged thirty-four at death, was admitted in November, 1866. She was entered as a congenital imbecile in weak health, unable to answer questions though able to speak a few words, was dirty in habits, ill-tempered, passionate, and at times violent. By dint of careful attention she improved in habits and conduct, and her bodily health improved. In 1873 she had an attack of excitement which lasted nearly six months, and during which, in spite of careful feeding, she lost weight. From this date till March, 1882, she remained in her usual mental condition. During the period of more than fifteen years that she had been an inmate of this asylum she had been free of physical ailment.—March 25th: Patient had taken food the day previously as well as usual, and seemed in her ordinary state of health when she went to bed. During the night her bowels were moved. The motion was reported as natural in colour, size, shape, and consistence, by the night attendant. After this she was rather talkative, and appeared as if pained. As she looked ill she was kept in bed. She refused breakfast. I saw and examined her with all the care I could shortly after 9 A.M. There were no marks on the body. Temperature 97°; pulse 80, very weak. The tongue was slightly furred, with a tendency to dryness. The heart's sounds were feeble. There was comparative dulness over the left lung, both anteriorly and posteriorly, and respiration was harsh; but no crepitation, mucous râles, or other abnormal sounds heard. The abdomen was examined, and nothing abnormal was detected. There was no increase in size, and no abnormality noticed by touch or percussion; the patient exhibited no fear of being examined; no tenderness on pressure. The patient seemed to have a tendency to sickness, though she did not vomit. I was at a loss to know what was wrong, but thought it probable that she was going to have an attack of acute chest disease. I ordered a mustard poultice to be applied to the left side, and liquid nourishment to be given to the patient. At noon, while sitting up taking some beef-tea, which she was doing with avidity, she suddenly fell back in bed, and had a slight epileptiform convulsion, her eyes turning round. She became sick, vomited the beef-tea she had taken, passed urine in bed, and died in a state of collapse within forty minutes.

*Autopsy, twenty-eight hours after death.*—Body free of marks; rigor mortis present; face and lips pale; pupils equal, rather dilated; thumbs inverted. Head: Brain examined, no abnormality noticed. Chest: Right lung free in cavity, very slightly congested; left lung very slightly adherent at apex by an old adhesion; left lung was slightly congested, principally posteriorly; structure of both lungs normal. Heart: Muscular substance normal, valves competent. Abdomen: There was a considerable amount of blood-tinged fluid in the abdominal cavity, and on the contents of the abdominal cavity being fully exposed, a large portion of the ileum and of the large intestine were seen to be quite black; there was, in fact, a twist of a large mass of intestine. Ligatures were applied to the lower ends of the duodenum and colon and the mass removed. Eight feet (measured) of the small intestine were found to be black and strangulated, and a foot of the descending colon was similarly affected. The intestine, though black, was found strong and fresh on traction, showing recent strangulation. There was no ulceration of intestine, and no abnormality of parietal

pneum. The liver, spleen, kidneys, uterus, and ovaries normal; the stomach and urinary bladder empty.

*marks*—I have endeavoured to eliminate extraneous and to condense the account both of the cases and autopsy from the reports in my possession so as to save the reader from needless mental exertion. In an asylum containing 400 to 450 patients, with an averaged death-rate of only 1 per cent. per annum, calculated on the average numbers sent, to have within two months three deaths from causes as are narrated above is a remarkable coincidence. Abdominal cases are about the most obscure, the most uncertain, and the most difficult to deal satisfactorily with most an axiom. The difficulty in diagnosing and treating physical disease in the vast majority of the insane is as it is, and in many cases even greater than, in dealing with children; no indication of the seat or nature of the affady can be communicated by the patient. In the three cases reported no aid of this sort was really available; in the first case, pain was complained of, but during most of the illness many vague complaints were made, and they were made only in a semi-coherent manner. In the second case active resistance to examination complicated matters; and in the third and last case real mental defect prevented the power of communicating symptoms. In the first two cases I suspected internal cancer from the general appearances, but was unable to localise it. In the last case, that of M. C.—, the yellowish tinge of the skin, sickness, and pain in the region of the epigastrium might be, and probably were, the result of the gall-stone complication. The great prevalence of gall-stones in the insane has been noted in other asylums as well as in this. Considering the gravity of the intestinal lesion, it seems rather astonishing that signs of bowel complication should not have set in earlier, and have been of a more intense character. The unformed character of the stools was noted; it this means really nothing, for I have seen in a case of very narrow stricture of the large intestine large solid and firm faeces passed, which must have solidified and formed in the lower part of the gut. In the second case the position of the cancer and its not in any way affecting the outer surface of the caecum are noteworthy points. I find that out of 539 deaths in this asylum (and the cause of death is not conjectured, but is ascertained by post-mortem examination) twenty-nine, or nearly 5 per cent., have been caused by cancer; of this number eleven have been due to cancer of the stomach or intestinal canal. I have not data to enable me to comment on the proportional death-rate in other similar institutions from this disease. Were a uniform system of recording, tabulating, and publishing the causes of death in asylums and hospitals in force, clearly stating where the result was ascertained by post-mortem examination, a comparison of such fatal diseases would help in forwarding our knowledge of their history and habitat. In the third and last case, the symptoms and post-mortem appearances clearly point to a very recent strangulation. I believe the effusion found in the abdominal cavity took place within three hours, between the time I examined her and her death. That the strangulation should have affected the parts it did seems strange to me. The largeness of the portion of intestine strangulated undoubtedly caused the rapidity of death; death in this case really resulted from shock.

## SALICYLATE OF SODA IN ACUTE ORCHITIS COMPLICATING GONORRHOEA.

By EDWARD HENDERSON, M.D., F.R.C.S. EDIN.,  
MUNICIPAL SURGEON, SHANGHAI.

THE marked and speedy relief of pain which follows the administration of salicylate of soda in rheumatic inflammation of the joints has been for some time past a matter of common clinical observation. The success which I have myself had with this drug in treating these affections led me in the autumn of 1880, while in charge of the Shanghai General Hospital, to give it a trial in a case of acute epididymitis occurring as a complication of gonorrhoea. Since then I have had but two satisfactory opportunities of repeating the experiment; I regard, however, the results obtained in these three cases as sufficiently good to warrant further trial of the remedy, and, indeed, entertain the hope of finding by

more extended experience that we possess in salicylate of soda a drug which exercises something very like a specific influence over the disease.

CASE 1 was admitted to the General Hospital on September 13th, 1880. The patient contracted gonorrhoea about three weeks previously. For a week the left testicle had been somewhat swollen and painful. On the 11th the swelling increased considerably, and the pain became severe and constant. On the 12th he suffered a good deal, and was unable to leave his bed; that night the pain prevented him from sleeping, and he had fever. On admission, at 10 A.M., his temperature was 102°. The left testicle was about four times larger than the right, and the scrotum covering it was red, being stretched and glossy in front, and somewhat oedematous below. There was great tenderness. The urethral discharge had disappeared. I thought the tunica vaginalis implicated, and regarded the case as probably a suitable one for treatment by puncture, as recommended by Mr. Smith and others. Salicylate of soda was ordered in twenty-grain doses hourly until the pain should be relieved. At 4.30 P.M. four doses had been taken—namely, at 11.10, 12.10, 1.10, and 4. He had sweated profusely, and the pain had greatly diminished. At 8 P.M. his temperature had fallen to 100°, and the medicine was ordered to be continued at intervals of four or six hours. He slept well that night without an opiate. On the following morning (the 14th) his temperature was 98.4°, and he felt quite easy while lying down. Pain had altogether left him on the 15th, and the urethral discharge returned on that day. There was no relapse.

CASE 2.—A police constable, seen by me for the first time on the morning of April 8th, 1881. Patient contracted gonorrhoea about a fortnight before that date. One of his testicles had been swollen and painful for five days, but, until the morning of the 8th, he had been able to do patrol duty; being then no longer able to walk, he was compelled to go on the sick list as suffering from venereal disease. The inflammation was confined to one testicle, which was between two and three times larger than the other; it was hard and very tender. The scrotal skin was red, but not glossy. The body of the testicle was perhaps affected in this case along with the epididymis. There was apparently no discharge from the urethra. The patient's skin was hot to the touch, and his tongue was coated. He was ordered salicylate of soda in twenty-grain doses every two or three hours according to the effect produced. The testicle was to be suspended in hot water from time to time during the day. By evening six doses of the medicine had been taken, and the pain was greatly relieved. The pain diminished, he said, after the first dose, when he began to perspire. In the afternoon he sweated profusely. On the following morning (the 9th) he was quite easy when lying down, and could bear the testicle to be handled freely. On the 10th he declared that all pain had left him, and asked to resume duty. The testicle was then distinctly less swollen, though still enlarged and indurated. Convalescence was uninterrupted. The urethral discharge returned, but I have not noted the date of its reappearance.

CASE 3 was first seen on June 15th, 1882. The patient contracted gonorrhoea a month before that date. For about eight days the right testicle had been somewhat swollen and painful, and at the same time the urethral discharge began to diminish, and finally disappeared. On the 13th the inflammation seemed to be subsiding; but on the 14th the patient walked a good deal, and by the evening of that day the testicle was much more swollen than it had yet been, and the pain was severe and constant. On the morning of my visit he was forced to remain in bed. He said he had had an "awful" night from pain, and had been quite unable to sleep. His temperature was 101.8° F.; pulse 90; tongue clean and dry. His bowels were confined, one small hard motion on the morning of the 14th, and the same on the morning of my visit (15th). The inflamed testicle was at least four times larger than the other, hard, and very tender. The scrotal skin covering it was dull red, stretched and somewhat glossy in front. I ordered twenty grains of salicylate of soda every two hours, avoiding any other treatment, local or by astringents. The medicine was taken at 11.30 A.M., 1.30, 2.30, 4.30, and 7 P.M. After the second dose he had some ringing in the ears and began to perspire. After the third dose sweating was profuse (the weather was warm). At 4.30 P.M., after the fifth dose, the pain was relieved. At seven o'clock I saw him again; his temperature was then 101.6°, and his pulse 84; the pain was

much less, and he could bear the testicle to be handled with tolerable freedom. On the following morning (16th) his temperature was 99.4°; pulse 88. He had taken two doses of the medicine during the night. He had slept well, and now complained only of slight pain confined to the upper part of the testicle. The testicle was much diminished in size, and fluctuation could be distinctly felt in front. His bowels were not moved till the evening of that day. Convalescence was uninterrupted and satisfactory.

In further trials of this plan of treatment I would advise that only acute cases be selected, the evidence of that condition being a distinct rise of temperature as ascertained by the thermometer. The dose of the salt should be not less than twenty grains, and should be repeated hourly until at least three doses are taken; afterwards the same dose may be continued at longer intervals.

Shanghai.

### THE CLINICAL CLASSIFICATION OF BACKWARD DISPLACEMENTS OF THE UTERUS.

By G. ERNEST HERMAN, M.B. & M.R.C.P. LOND.,  
ASSISTANT OBSTETRIC PHYSICIAN TO THE LONDON HOSPITAL,  
PHYSICIAN TO THE ROYAL MATERNITY CHARITY, ETC.

(Concluded from p. 981.)

LEAVING these cases, we come to those in which the displacement produces or modifies symptoms.

2. The second class I would make comprises those cases in which the retroversion or retroflexion is associated only with symptoms caused by slight yielding of the pelvic floor. It is in these cases that mechanical treatment is most successful. When backward displacement of the uterus is the cause of symptoms, in the majority of cases they are of this kind, and treatment is successful in proportion as they are of this kind only. The uterus may be either retroverted or retroflexed. It may be so retroverted that it is literally upside down, the cervix being above and the fundus below: a case has been recorded<sup>1</sup> in which the fundus protruded at the anus when the patient defecated. Or it may be retroflexed, being so bent that the posterior surface of the body forms an acute angle with that of the cervix. But so long as the uterus is free to move, and its walls of natural thickness, it makes no difference whether it be bent or straight, or, if bent, whether little or much. Although at the posterior surface the bend may form an angle, there is no angle in the canal. When we examine a case of this class we find the uterus displaced in either of the ways just mentioned; but it is quite movable, neither body nor cervix is enlarged, and there is no tenderness. The only symptoms the patient complains of will be a pain in the sacral region, and also more diffused pain, referred to the loins, lower abdomen, and thighs, and described as a dragging, bearing-down pain, a feeling as if something were falling from her. All these uncomfortable sensations disappear when the patient lies down—that is, when the intra-abdominal pressure is taken off; a point upon which I would lay particular stress. Generally the patient will complain of having to micturate with undue frequency. The menstrual function will be unaltered. There will often be leucorrhœal discharge, because the conditions (subinvolution, &c.), which weaken the pelvic floor, also favour the occurrence, and retard the disappearance, of vaginal catarrh. It is also very common to hear of constipation and dyspeptic symptoms, dating back to a time when the patient was free from uterine trouble. This is because the straining to pass scybala, which results from constipation, is a frequent cause (generally co-operating with others, sometimes perhaps alone) of these displacements. It is in these cases, in which the symptoms are those, and those only, which slight prolapsus produces, and in which the only morbid condition present is the displacement (including under that term not only the alteration in the position and shape of the uterus, but the changes giving rise to it), that mechanical treatment is most brilliantly successful. A pessary which pushes up the uterus relieves the symptoms at once. It matters nothing, in this class of cases, what the effect of the pessary upon the shape of the uterus may be. It may straighten the uterus or leave

it bent; but if it pushes the uterus up, and remains in its position without injuring any part by its pressure, it will relieve.

3. The next class of cases includes those in which there is not only displacement, but congestion of the uterus. This congestion may be either (a) a result, (b) a cause, or (c) an accidental accompaniment, of the displacement. (a) When the body of the uterus sinks down between well-developed utero-sacral ligaments, its veins, which run in the broad ligaments, will, if the uterus be forced down strongly enough, be compressed against the utero-sacral ligaments, and the return of blood from the uterus thus be impeded.<sup>2</sup> In such cases the displacement causes the congestion. (b) There is also reason to think that by congestion of the uterus and the other structures having the same vascular supply, the pelvic floor may become so relaxed and weakened as to allow the uterus to fall backwards. In these cases the displacement is the result, not the cause, of the congestion, the relation being shown by the fact that when the parts have returned to a normal condition the displacement disappears. Thirdly (c) we have no ground for supposing that retroflexion of the uterus confers any immunity from uterine congestion, and, knowing that retroversion or retroflexion exists in a certain proportion of healthy women, it is obviously possible that they, as well as those whose uteri lie more nearly in the axis of the pelvic brim, may become the subjects of uterine congestion, which yet has nothing to do with the displacement, either as cause or as effect, the relation between the two being simply that of coincidence.

It is extremely difficult to estimate in what proportion of cases congestion accompanying backward displacement is either its effect or its cause. Recovery while mechanical treatment is being used, or relief following its application, does not prove that the congestion is the result of the displacement; for the symptoms of prolapse may be relieved by mechanical support, in cases in which the congestion is quite independent of the displacement.

In these cases the symptoms are those of prolapse *plus* those of congestion. The pain is greater and is not immediately relieved by lying down. There is hæmorrhage, the menstrual flow is increased in quantity, prolonged, or recurs with undue frequency; and is attended with more than usual pain. The body of the uterus is swollen, tender to the touch, and there is pain on defecation. Micturition is attended with cutting or burning pains, and there is irritability of the bladder. It has seemed to me that pain and hæmorrhage in these cases (as, indeed, in some other kinds of uterine disease) stand to some extent in antagonism to one another. When there are abundant losses of blood, the congestion is thereby diminished, and the pain is less. When uterine hæmorrhage is not more than is customary for the patient, pain and tenderness are often very pronounced symptoms.

In cases in which congestion is the result of the displacement, it can be cured by raising the uterus, so as to relieve the broad ligaments from pressure. This is most efficiently done by a pessary which anteverts the uterus, or at least keeps it in the axis of the pelvic brim. A Hodge's pessary will often do this, and when it does, it removes the symptoms with striking rapidity and completeness. But the Hodge's pessary is formed of a thin and hard bar. If it fail to antevert the uterus—if, as it is represented in some books as doing, it presses directly on the tender congested uterus—it will aggravate instead of relieve the symptoms. This is an essential and practical difference between this class of cases and the one last mentioned: in the former, anything that pushes up the uterus will relieve, whether it does so by directly pressing on it or not, and it matters nothing whether that organ is straightened or remains bent. In the latter a thin hard pessary, if it presses directly on the tender uterus, will do harm; to do good it must antevert it; and if a retroflexed uterus be anteverted, the flexion will be removed. Hence relief often coincides with the removal of flexion, although that condition has nothing to do with the production of the symptoms. But often it is difficult, and sometimes impossible, to get a Hodge's pessary to antevert the uterus, and we find the best fitting instrument that we can adjust only raises the body of the uterus by pressing directly upon it, and consequently causes discomfort. In such cases I have found the best instrument to be a thick indiarubber

<sup>1</sup> Edinburgh Medical and Surgical Journal, 1854, p. 336.

<sup>2</sup> I would ask permission again to refer to my paper read before the Obstetrical Society of London, and which will be published in the forthcoming volume of its Transactions, for fuller exposition of the reasons which induce me to attach importance to this condition.

z, which, it is true, presses on the uterus, but, being thick & soft, its pressure is bearable, and as it raises the uterus, relieves, although not so thoroughly as an instrument which keeps the organ anteverted.

Lastly, we have cases in which the displacement is combined with other morbid conditions of which it is neither the cause nor effect. Backward displacements of the uterus are, I have already stated, more commonly associated with morbid phenomena than is antelexion, because the injuries consequent on childbirth which predispose to inflammatory disorders of the uterus and its adnexa, also predispose to prolapse and backward displacement. In such cases the symptoms may or may not be modified by the displacement. There may be any degree of prolapse, or if there be congestion, the symptoms so caused will add to the patient's suffering. Prolapse implies increased mobility of the uterus; movement of the body of the uterus involves movement of the uterine tubes and ovarian ligaments, and movement of these parts will be communicated to the ovary. Movement of the inflamed parts produces pain, and, therefore, if ovaritis, peritonitis, or perimetritis be present, abnormal mobility of the uterus, by producing movement of the inflamed parts, will aggravate the pain. Treatment which keeps the uterus in its normal position, and so limits its range of movement will lessen the pain. It may thus happen that mechanical support in a case of backward displacement of the uterus will relieve symptoms not produced by the displacement. These form a group of cases that must be recognised. In them we cannot promise the immediate and complete relief which mechanical treatment gives to symptoms entirely dependent upon a mechanical cause, although sometimes the patient's discomfort may be lessened by a pessary. This group of cases, it will be obvious, comprises diverse combinations of morbid conditions. It can only be defined as including those cases of backward displacement of the uterus which do not come under either of the three former categories.

To sum up the purport of this paper. Its object is to classify cases of backward displacements of the uterus in a manner which shall assist us in their treatment, to divide them into groups the differences between which are real and practical. The classification suggested is the following, its application to practice being at the same time epitomised:—

1. *Retroversion and Retroflexion without symptoms.*—In probably the majority of cases of retroversion and retroflexion there are no symptoms arising from the peculiarity in the shape or position of the uterus. Therefore, in order that this displacement shall call for treatment, it is not enough that the patient shall complain of something, but the symptoms must be such as the displacement is known to produce—i.e., symptoms of which we can predict relief by mechanical treatment.

2. *Retroversion and Retroflexion without Congestion.*—In most of the cases in which backward displacement of the uterus is the result of morbid changes the symptoms are only those of a slight degree of prolapse. Such cases are at once relieved by an instrument which pushes up the uterus. It matters nothing what is the shape of the uterus, or what the effect of the pessary in altering its shape. In proportion as cases approach this simple type, so is the certainty of relief from mechanical treatment.

3. *Retroversion and Retroflexion with Congestion.*—In a smaller number of cases of backward displacement of the uterus there is also congestion of that organ; the symptoms of which condition are then added to those of simple prolapse. In such the pressure of a hard pessary upon the body of the uterus will aggravate the patient's discomfort, and the maximum of relief will only be gained by a pessary which anteverts the uterus. In some few cases the congestion is the direct result of the displacement, and in such immediate and complete relief will follow anteversion of the uterus.

4. *Retroversion and Retroflexion complicated with other Morbid Conditions.*—Many cases are complex, the displacement coexisting with other morbid conditions. It is only in the simple cases that benefit from mechanical treatment can with certainty be predicted.

West-street, Finsbury-square, E.C.

ROYAL MEDICAL BENEVOLENT COLLEGE.—At an extraordinary general meeting of the governors of the College to be held at 37, Soho-square on the 20th inst., at 3 o'clock, the Council will propose certain alterations in By-laws 2, 23, 24, and 25, to meet the determination of the Council to establish a system of "House Masters."

## EUCALYPTUS ROSTRATA AS A REMEDY FOR DIARRHŒA.

BY T. J. HUDSON, M.B., L.R.C.P. LOND.,  
RESIDENT MEDICAL OFFICER, LEEDS PUBLIC DISPENSARY.

I AM induced to bring the above drug more prominently before the notice of the profession owing to the very marked success its administration has met with in my hands in over two hundred cases of various forms of diarrhœa during the past summer. Not that it is by any means a new remedy, though noticed cursorily in the text-books. Eucalyptus rostrata (Australian red gum) was first brought into Europe by Sir Ranald Martin, and occurs as imported in dark-red hardish masses, its essential principle being tannic acid. It is supplied in a pure form by Messrs. Harvey and Reynolds, of Leeds. The preparations found most useful have been a concentrated decoction (strength 1 in 20), and a dilute (strength 1 in 40) made by boiling the powdered gum in distilled water for ten minutes, and filtering while hot, and a syrup (strength 1 in 3). For a moderately severe attack in the adult I commence with half an ounce of the dilute decoction every two hours. If after four doses no improvement results, the same quantity should be given every hour for four times, and if still little effect is apparent, I order half an ounce of the strong decoction every two or three hours. In the vast majority of suitable cases an abatement of the attack now occurs, going on rapidly to a cure, when the same dose should be ordered every five or six hours, only gradually discontinuing the remedy. In an acute case it is best to commence with the strong decoction at the first, half an ounce every two hours, and at times every hour, increasing the time as above. The syrup may be given to children in doses of five to twenty or more drops three or four times a day, but, mindful of the tendency of sugar or mucilage to run into fermentation, seldom prescribe it, preferring small doses of the dilute decoction (thirty to sixty drops) guarded with spirits of camphor or some simple carminative every few hours, pushing it if needful. In many of the worst cases occurring in children, when all other remedies have failed, this alone has effectually stopped the alvine flux. The forms of diarrhœa alone benefited by this drug are as follows—viz.:

1. That arising from want of proper assimilation, the unaltered food causing irritation, chiefly of use after this or other harmful substance has been removed from the alimentary canal. 2. The bilious. 3. The congestive, an inflammatory state of mucous membrane existing, most useful in the latest stages, that the result of sewer gas also coming under this head. 4. Summer or sporadic cholera. 5. That the result of amyloid degeneration of the intestines, usually the small. 6. The chronic or white flux; of great service in this variety.

The above applies equally to children. In cases of intermittent diarrhœa, the patient having an attack every two or three days for some time, while well in the interval, the drug is very effectual, given as above twice or thrice daily. It is also of service in those cases which, when first seen, present great depression, where the offending cause must be allowed to take its course, and where opium is contra-indicated. The good results obtained are not simply owing to the tannic acid contained therein, as many cases unaffected by the latter are soon cured by the red gum, partly, no doubt, owing to the far less irritant properties of the decoction. It is contra-indicated where there exists much acidity or flatulence, and if the griping pains are very severe a few drops of laudanum may at first be added with advantage, but omitted so soon as this symptom is in abeyance. It adheres firmly to mucous surfaces, diminishing their secretion, coagulating the albumen, the uncombined portion serving to constrict and contract the vessels of the gut, and to give the latter tone.

As tannic acid diminishes the solvent power of gastric juice, the gum should not be given too near food. Its taste is rarely objected to, and can be improved by the addition of spirit of chloroform. Lastly, its cheapness is a desideratum, more especially in dispensary and hospital practice.

*Nulla autem est alia pro certo noscendi via, nisi quamplurimas et morborum et dissectionum historias, tum aliorum tum proprias collectas habere, et inter se comparare.*—MORSEANI *De Sed. et Caus. Morb.*, lib. iv. Proculum.

#### ST. THOMAS'S HOSPITAL.

POPLITEAL ANEURISM CURED BY THE USE OF ESMARCH'S BANDAGE, FOLLOWED BY DIGITAL PRESSURE.

(Under the care of Mr. SYDNEY JONES.)

W. H. E—, aged thirty, a clerk (formerly a farmer), was admitted under the care of Mr. Sydney Jones on June 19th, and discharged cured on July 19th, 1882. Three years ago he was under Mr. Sydney Jones' care for disease of the right elbow joint, which was excised. Ten weeks before admission, after straining himself whilst running, he noticed stiffness in the left leg, increased by walking. Two or three weeks later he began to notice considerable throbbing pain behind the left knee, shooting down into the calf of the leg; this was very violent at times. About a week later he noticed a throbbing swelling behind the same knee. He went to a medical man and was treated for a fortnight by flexion of the knee joint and rest in bed, but for the last fortnight has only been resting without special treatment; there has been no improvement in the swelling. The patient, a tall, strong man, with reddish hair and beard, complained only of the swelling behind his left knee and the pain caused by it. On examination this swelling presented the characteristics of aneurism of the popliteal artery, and was about the size of a large hen's egg, and similar in shape. There was marked expansile pulsation, arrested by pressure on the artery, above, and a loud bruit. Its long axis corresponded with that of the artery, and it occupied chiefly the lower part of the space. The circulation was irritable, the pulse being full, quick, and rather hard. No evidence of arterial degeneration in other parts of the body. Examination of urine showed absence of albumen. The right elbow was ankylosed, but in a good position, and patient was able to feed himself comfortably, easily reaching his mouth with the hand. The morning after admission he was given three minims of tincture of aconite in an ounce of water, and this was repeated three times daily until the 23rd, when his pulse was quieter and more compressible. At a quarter before 3 P.M. on the 24th Esmarch's elastic bandage was applied, the patient standing up to allow the sac to fill. The bandage was applied gradually from the toes upwards; the aneurism, however, not being included. The bandage was fastened round the upper part of the thigh. The elastic ligature was not used. This was kept on for one hour and a quarter, and during the last half of the time it was necessary to keep patient partially under chloroform. When the bandage was removed pulsation recommenced, so digital pressure was at once started, and kept up for eleven hours, when all pulsation had ceased; at the end of nine hours the pulsation had much diminished, but did not stop until two hours later. During the last three hours patient vomited considerably.

June 27th: No return of pulsation. The aneurism much smaller. Several branches of collateral circulation detected. The general condition of patient good.

July 4th: Left foot still a little colder than the right. Pulsation of the posterior tibial artery indistinct. Is still kept in bed with his left leg semi-flexed and placed on its outer side. An elastic stocking was ordered, reaching from the toe to above the middle of the thigh. A few days later the patient was allowed to get up, and left with the aneurism cured on July 19th. As regards internal treatment, tincture of aconite, given on the 19th, was stopped on the 23rd, and from that date until July 1st he took ten grains of iodide of potassium three times a day. On July 1st the aconite was repeated, and the patient took a similar dose for a few days.

INJURY TO THE HEAD; IN WHICH RECOVERY OF CONSCIOUSNESS WAS FOLLOWED BY RELAPSE AND DEATH TWELVE DAYS LATER, AND IN WHICH NO CEREBRAL LESION COULD BE FOUND POST MORTEM.

F. S—, aged seven, was admitted, under the care of Mr. Sydney Jones, on Jan. 6th, 1882, with the following history:—At 4.30 P.M., on the 5th he fell over the balustrade at home, striking the nape of his neck on the stair. Before the fall he had been in his usual health. Immediately afterwards he lost consciousness, and remained unconscious for about three hours. He is then stated to have recovered, and recognised his parents. He complained of pain at the back of his head, and vomited two or three times. Later in the evening he again became unconscious, and was stated to have had fits, which continued at intervals during the night. During these attacks he struggled violently, screamed out, and ground his teeth; he also vomited frequently.

When brought to the hospital next morning he was in one of these attacks, and was restrained with difficulty, screaming out loudly and grinding his teeth. There was a slight bruise at the back of the neck, and on pressing over or near this the convulsive movements were set up. There was no sign of fracture of the skull. The pupils were very large, equal, not acting to light, but varying in size at times. Temperature 101°.

Jan. 7th: During the night he had occasionally tossed himself about in bed, and screamed out. He had only taken a few teaspoonfuls of milk and a purge. In the morning he was still unconscious, with a dry tongue and mouth. He was rather irritable, lying on his side, with his limbs flexed, and resisting any attempt to examine him. Pulse 100, weak. The temperature, which last night was 100°, was now 101.6°.—8th: The patient still lies in an unconscious condition, making only slight movements occasionally, and these principally on the left side. The left hand appeared the colder, but when tested by the surface thermometer showed little difference: right, 97.6°; left, 97.4°. His breath was foul. There were sordes on the teeth. The pulse was 108, almost imperceptible, and intermitting: temperature of body 102.6°.—10th: He slept quietly during a good part of the night, and in the afternoon showed some signs of returning consciousness, making an attempt to put out his tongue when told to do so. He slept a good deal during the day, but was very restless, tossing about from side to side when awake; the mouth was cleaner, he drank milk in fair quantities, but his pulse was extremely feeble and his hands cold: the temperature, morning and evening, was 97.8°.—11th: No further improvement. He had taken beef-tea, jelly, milk, and a little brandy. In the afternoon the pulse was 148, almost imperceptible, and he was very restless, whilst the pupils were still equal, and there was no evidence of optic neuritis. Later in the day he became more restless and violent, throwing himself about, and knocking his head against the head of the bed; morning temperature 97°. Two nutrient enemata were given.—12th: Passed a fairly quiet night, and this morning appeared to recognise his parents, but did not speak. Morning temperature, 96.8°; evening, 96.8°.—13th: Appeared to understand, and protruded tongue when told to do so. Morning temperature, 97.2°; evening, 98.4°. Took more fluid nourishment and a little custard pudding. A blister was applied to the nape of the neck; and dressed with mercurial ointment.—14th: Temperature still subnormal.—15th, 11 P.M.: Extremities cold. Pulse running, at times almost imperceptible. The respiration, which had been slow and sighing, was then rapid and difficult. Had taken food well. Morning temperature, 97.2°; evening, 98.4°. During the 17th he appeared somewhat better and more conscious, taking a fair amount of food. About 12 o'clock at night he became worse, and his extremities very cold. A nutrient enema which was given was not retained, but he took some brandy, milk, and egg by the mouth; after this there was an action of the bowels, but no general improvement; and he died quietly at 4.45 A.M. on the 18th.

The post-mortem examination did not throw any light upon the case. The brain appeared in every respect natural, excepting that the organ contained rather more blood than usual, the puncta vasculosa being well marked. No hæmorrhage; no meningitis; no tubercle; no sign of softening. Skull and vertebrae without sign of injury; and cervical portion of cord apparently healthy. In the anterior border of left lung there were a few patches of broncho-pneumonia; lungs and internal organs otherwise normal. It is regretted that no microscopical examination was made of the nerve structures.

## LIVERPOOL ROYAL INFIRMARY.

NO CASES WHERE BOTH BREASTS WERE REMOVED FOR CARCINOMA; REMARKS.

(Under the care of Mr. REGINALD HARRISON).

CASE 1.—Mrs. M'C—, aged fifty-one, was admitted on Oct. 27th, 1881, with the following history:—About twelve months previously patient noticed a slight hardness in the left breast, which was followed in six weeks by retraction of the nipple. Shortly afterwards a similar hardness commenced in the right breast. The patient was a healthy looking woman, married, with one child. In each breast there was a well-marked scirrhous carcinoma, with retraction of the nipples, but no extension into the axilla. On Nov. 1st Mr. Harrison removed the right breast, and on Dec. 7th, when the patient had completely recovered from the first operation, the second breast was removed. On Jan. 5th, 1882, she was able to leave the infirmary, the wounds having completely healed. In the October following the patient reported herself as being quite well, and without any sign of a return of the disease.

CASE 2.—Mrs. R—, aged fifty-two, was admitted in November, 1881, suffering from a scirrhous carcinoma of the right breast with retraction of the nipple. The hardness had been noticed for eight months previously. She had a very healthy appearance. There were no enlarged axillary glands. On the 25th the breast was removed, and in nine weeks the patient was able to leave the infirmary. She seemed very intolerant to the carbolic applications. In June, 1882, she noticed some hardness in the other breast, but nothing was done, as she thought it was inflammatory and would disappear. In September she returned to the infirmary, when the left breast was found extensively infiltrated with cancer. The axilla was free. On September 13th, 1882, the breast was removed by Mr. Harrison. She made a good recovery, and was able to leave the infirmary on October 27th.

Mr. Harrison remarked that these were the only two instances in his practice where he had removed both breasts for scirrhus. In both cases the patients presented a singularly healthy and robust appearance, in fact, to look at them before making an examination of the breasts he should have selected them as typical examples of what healthy-looking middle-aged women should be. Still, there could be no doubt, either on clinical or histological grounds, that they were seriously infected with cancer. So far as the operations were concerned, no patients could have done better. Antiseptics were employed, and no untoward symptoms were met with. The second patient on each occasion showed an intolerance to carbolic acid, which rendered its abandonment necessary before repair had sufficiently advanced; still, she made an excellent recovery. Cases of this kind were interesting, not only as illustrating what operative surgery is capable of doing in the case of rapidly growing tumours, but as bearing upon the whole subject of infection by malignant growths.

## Medical Societies.

### ROYAL MEDICAL & CHIRURGICAL SOCIETY.

#### *Resection of Portions of Intestine.*

THE ordinary meeting of this Society was held on the 12th inst., Professor Marshall, F.R.S., President, in the chair. The paper of the evening, by Mr. Treves, of the London Hospital, was a careful and clear exposition of the subject of resection of the intestine, and its reading was followed by a debate that was prolonged beyond the usual hour of adjournment. Several pathological preparations in illustration of the subject were exhibited from St. Thomas's Hospital and University College, and a large collection of the instruments employed in abdominal operations were also shown by Mr. Lund and Mr. Meredith.

The following is an abstract of the paper on Resection of Portions of Intestine, by Mr. FREDERICK TREVES, F.R.C.S. Portions of gut have been excised for various diseased conditions from all parts of the tube, from the pylorus to the

rectum. Among the illustrative cases given of the various operations is Kœberlé's, who excised two metres of the small intestine for multiple stricture with perfect success. In properly selected cases, resection would appear to be indicated in some forms of intussusception when all other means have failed, and when on opening the abdomen, the invagination is found to be irreducible; in gangrene of gut after strangulated herniæ, in gangrene after some forms of internal strangulation, in non-malignant strictures of the small and large intestine, and in malignant strictures that are yet local. Other things being equal, the mortality after resection would appear to depend more upon faults in the details of the operation than upon any other single cause. There are two procedures: in one an artificial anus is established after resection; in the other, the two ends of the divided gut are united by sutures, and the mass returned into the abdomen. The former method has been the more successful. There are many objections, however, to an artificial anus, especially of the small intestine, and there appears to be no reason why the latter method should not prove the less fatal if the technical defects of the procedure be remedied. The operation of uniting the bowel after resection presents these difficulties. It is not easy to maintain the two ends of the gut in accurate apposition while the sutures are being introduced. The sutures are apt to be irregular. The gut above the obstruction is usually much dilated, while that below is shrunken, and it has been found almost impossible to unite well these unequal parts. One of the most common causes of death, therefore, after the operation is due to escape of intestinal contents at the suture line. There is no reason, however, why the escape should not be as surely prevented as it is in cases of pyloric resection. "To meet some of the difficulties of the operation I have ventured to introduce the following appliance:—The gut above the part to be resected is secured by a special clamp lined with indiarubber, to avoid undue compression of the bowel. The gut below is secured in like manner, and the obstructed or gangrenous part is excised. The corresponding ends of the two clamps are then united by transverse bars, so that they form with the clamps a rigid square frame. By means of this frame the two divided ends can be very accurately approximated, and can be firmly retained in position while the sutures are being applied. As it is difficult to apply sutures to collapsed gut a sausage-shaped indiarubber bag about three inches long is used, that can be distended to four or five times its natural size through a small tube inserted in the centre of its long axis. This bag is sufficiently distended to make it firm, and one end is introduced into the upper segment of the divided gut, while the other is introduced into the lower segment. The tube through which the bag is dilated thus occupies the suture line. After being introduced the bag is dilated to a good size. By this means a firm plug is introduced into the gut so as to form a substantial basis over which to apply the sutures. Moreover, by increasing the degree of distension of the bag, all inequalities in calibre between the two segments of the bowel can be overcome. Before the last sutures are applied the bag is emptied of air and is withdrawn, it being capable in its shrunken state of being drawn through a hole of the dimensions of a No. 12 catheter. If the sutures are properly applied—i.e., if the mucus membrane be not included in the stitch—there should be no danger of wounding the bag. At least fifteen or twenty sutures should be used. By means of this appliance it is possible to excise portions of the colon through an incision in the middle line." In cases of stricture of the colon it is often impossible to diagnose the exact seat of the obstruction, and under such circumstances the abdomen has been several times opened in the middle line, and the obstruction having been found, a second operation has been performed in one or other loin. Resection of the gut from the loin presents many difficulties, and can scarcely be performed without establishing an artificial anus. If colectomy were always performed through the middle line it would, in cases of doubtful diagnosis at least, render one operation only necessary. The greatest fatality has been found in those cases of resection of the colon where the abdomen was first opened in the middle line, and the gut subsequently removed from the loin through another incision. The author lately resected some two inches of gut from the middle of the descending colon for epitheliomatous stricture through an incision in the middle line. The divided ends of the bowel were united by means of the appliance described, and the gut returned into the abdomen. The man had had symptoms of obstruction for some months, and was in

*extremis* when the operation was performed. He died in twelve hours. At the post-mortem the gut at the suture line was found fully distended with fluid fecal matter, yet not the least trace of that matter had escaped from the intestine. The case serves to demonstrate that portions of the colon can be resected through the middle line, and that the gut may be so united as to prevent all escape of contents.—The PRESIDENT, in inviting discussion upon the paper, drew attention to a series of preparations on the table of various morbid conditions of the intestines from the museums of St. Thomas's Hospital and University College; and also to a large selection of instruments used in abdominal operations, exhibited by Mr. W. A. Meredith of London, and Mr. Lund of Manchester.—Mr. BRYANT, in congratulating Mr. Treves upon his case and contribution to the subject, proposed, in the first place, to offer a little friendly criticism upon it. He regretted that Mr. Treves in dealing with the case had not performed lumbar colectomy, for the case was one of chronic obstruction, and clinically the probabilities were in favour of the disease being in the descending colon, so that if the lumbar incision had been made he would have come upon it and readily removed it. Of the two procedures, abdominal and lumbar, the latter was to be preferred as an exploratory operation, and even for colectomy, for at least six inches of the colon can be readily dealt with through the lumbar incision—i.e., if the bowel be not over-distended, as it was not in Mr. Treves' case. He praised the instrument invented by Mr. Treves as an admirable device; but it must not be forgotten that in cases of intussusception or internal hernia great lengths of bowel have to be dealt with, whilst the distended and inflamed condition of the bowel above the obstruction would be very difficult to unite with the distal collapsed segment. In cases of stricture, unless the diagnosis can be made very early—i.e., before there is obstruction—the same difficulty in uniting the two segments would be met with. In Mr. Treves' case the cæcum (as is usually the case) was more distended than the colon immediately above the stricture, and this being so the clamp could be applied more readily. He also urged that in most cases of internal strangulation the inflamed condition of the gut would render it far more liable for stricture to ultimately follow upon its successful suture from contraction of the wound, just as stricture ensues in those cases of intussusception where the invaginated segment separates by sloughing. It was for this reason that in his own case of colectomy he (Mr. Bryant) preferred making an artificial anus to attempting to suture the severed ends of the bowel; although he admitted that Billroth's experience of pylorus resection showed that in cases of limited annular stricture such suture might be safe. Again, how would the mesentery be dealt with when a large piece of small intestine had to be excised? Although not prepared at present to adopt the measure, he trusted that his objections might be overcome and his opinion changed. Mr. Bryant added, that in the three cases (including Mr. Marshall's) where abdominal section had been first done and then lumbar colectomy, he had felt that a better result might have followed had the lumbar operation been chosen for exploration in the first instance.—Mr. BARKER pointed out that wounds under aseptic conditions showed no tendency to contract, union taking place by first intention. That was true of wounds in the skin and serous membranes, and was quite as applicable to the intestine. Nor did he think many cases of intussusception when separation took place with recovery were followed by stricture; and he referred to one case where Dr. Peacock said that no symptom of obstruction followed, although the patient survived the intussusception many years. Nor does stricture occur after attacks of typhlitis and ileus. He did not think that Mr. Bryant's inference was justified.—Mr. HOWARD MARSH alluded to the continued advances in abdominal surgery, and pointed out that in Mr. Treves' case inference came, as in so many cases, too late. The patient was so exhausted that colotomy even might have been fatal. He looked forward to the time when an early recognition of these cases would lead to very different results. But no surgeon hesitates to operate on strangulated hernia because it is too late to afford relief; and such a contingency must often occur. The case of cancerous stricture of the colon in which he (Mr. Marsh) had performed abdominal section, was that of a woman, aged forty, who was suddenly taken with intestinal obstruction when at work. An accurate diagnosis was impossible, and looking to the age of the patient alone colotomy might have been preferred. The

case proved to be annular stricture of the sigmoid, and made an artificial anus in the gut above it. Mr. Marsh narrated cases which had recently come before him, to show how little reliance could be placed on the numerical method for diagnosing the site of a stricture in a subject beyond middle age. (1) A man, aged fifty, suddenly seized with symptoms of obstruction whilst walking in the street. Colotomy performed without relief. Post-mortem: abscess in connexion with appendix vermiformis, which had burst into the peritoneal cavity. (2) Obstruction in an elderly lunatic, presumed to be in sigmoid; no operation. Post-mortem: two gall-stones impacted at ileo-cæcal valve. (3) Case with history of increasing constipation; from age of patient stricture thought to be in colon, but as its precise seat was uncertain right colotomy was done. There proved to be ulceration of the lower six inches of the ileum. Such cases showed that the numerical method might be carried too far in diagnosing the seat of a stricture in the large bowel; and, further, they demonstrated the advantage of the median incision over a colotomy which is done without certain knowledge of the position of disease. The difficulty raised by Mr. Bryant might not prove to be well grounded, and he thought that eventually the abdominal operation would come to be preferred.—Mr. HARRISON CRIFFS said that although Mr. Treves had demonstrated its possibility, it would have to show a fair probability of success in the operation before it could be generally adopted; and in the case he related death occurred before the separation of the sutures, or inflammatory softening might have led to fecal extravasation. He himself had practised excision of the rectum in cases of cylindrical epithelioma, in which case it is right not only to relieve the obstruction but to remove the diseased mass, which can be done without fear of recurrence. He would prefer making an artificial anus after resection of the bowel to the attempt at suture of divided ends on account of the risk of the latter, with the possibility of subsequent stricture. Stricture follows removal of the lower end of the bowel, and can only be obviated by continued use of bougies—a measure, of course, inapplicable to the intestine within the abdomen. In Mr. Marshall's case an artificial anus was made, but it would have been better still had the diseased part been excised.—Mr. MCKAY observed that abdominal surgery was undergoing a great change, and now that we know abdominal section can be done without much risk, operations on the intestine will be more frequent. Sutures of wounded intestine did well; he had three cases in which recovery took place, and no stricture followed; this being so, he thought Mr. Treves was right in saying that success mainly depended on the manner in which the details of the operation were done; fecal extravasation need not be feared if care be taken. Nor did he agree with Mr. Bryant as to the frequency of secondary strictures; for if it were so could the immunity from stricture after dysentery, where large sloughs separate, be explained? Apart from this, he believed with Mr. Barker that the operation of suture could be done with very little risk of subsequent inflammation. After hearing the paper and seeing Mr. Treves' instrument, he should be inclined to adopt his suggestion.—The PRESIDENT said that as regards this operation of resection of the bowel, they were on the verge of improvements, and that Mr. Treves' contribution was valuable as an effort to advance the subject. He thought with Mr. Bryant that there would be considerable difficulty sometimes in getting the dilated bowel into apposition with the collapsed part—a difficulty which he feared would not be wholly met by Mr. Treves' instrument, for he could not see how the dilated part could be made to contract. It was just possible in future that electricity might be called in to cause such contraction of the upper segment and dilatation of the lower, so as to approximate the calibre of the two portions. In his own cases he was perfectly sure that no instrument could have made them equal. Mr. Treves' clamp was a great improvement on Martigny's, which did not bring the divided ends together. He agreed with Mr. Treves as to the use of a large number of stitches, and suggested that the packings following the union of the two unequal-sized ends of the bowel might be met by putting the sutures in each end at unequal distances apart. Although the formation of an artificial anus was simpler and safer, they must not be content with that, but seek a better method, nor be deterred by some failures; and there was sufficient to encourage these endeavours. He agreed with Mr. Barker as to the slight fear of stricture following on suture, especially as constriction

to granulations. He was still of opinion that in a case of chronic obstruction (and Mr. Marsh's cases were a ones) the lumbar operation was preferable; but this was only his view, and he might come to prefer the median incision. In his own cases he failed to withdraw the diseased stomach through the median incision; it was at the lower part of the colon, and he did not think of dividing the peritoneum.—Mr. TREVES, in reply, said that the case he had alluded to was an obscure one, there being no symptoms pointing to obstruction of the descending colon; and it was under the impression that the disease was in the ileum that he opened the abdomen. Had he felt sure of its actual seat he would have done the lumbar operation. In reply to Mr. Marsh's objections, he referred to Koberlé's case, where two thirds of intestine were successfully removed, the mesentery being sutured with twenty-four ligatures. The dilating bag, which he had used in his own case, considerably aided in reducing the collapsed bowel to the size of the distended stomach. Again, the most successful cases of resection had been those of gangrene after strangulated hernia, for which there had been six successes out of eight operations. Subsequent stricture was very rare in intussusception. Leichstein, who collected upwards of 900 cases, says that fatal outcome followed in only 3 to 4 per cent. of the cases of spontaneous separation of the invaginated bowels. He agreed with Mr. Marsh's remarks about too great reliance being placed on statistics; and it must be remembered that in many cases of chronic obstruction the onset of symptoms is often acute. The risk of extravasation could not be so great in the case of the intestine as in that of the pylorus, when it had been quite prevented. In cases of great disparity in calibre between the two portions it would be well to make an oblique section of the lesser segment, as in pylorus operations. Lastly, in strictures of the small intestine no treatment was available except that afforded by resection.

#### PATHOLOGICAL SOCIETY OF LONDON.

*Acute Dilatation of Stomach.*—*Osteitis Deformans.*—*Malformed Heart.*—*Rachitic Osteomalacia.*—*Stricture of the Intestine.*—*Malformation of Auricle.*—*Symmetrical Gangrene.*—*Cancer of Esophagus.*—*Noisy Respiration.*

THE ordinary meeting of this Society was held on Tuesday, December 5th, the President, Dr. Wilks, in the chair. Several specimens, and a case of special interest were shown, namely, a case of extreme rachitic osteomalacia by Mr. Arnwell, which, at the suggestion of Mr. R. W. Parker, was referred to the Rickets Committee. The body of a child who had died with symmetrical gangrene of the extremities was exhibited by Dr. Southey, and the larynx of a child with swelling of the epiglottis producing a peculiar form of dyspnoea by Dr. Lees.

Mr. HENRY MORRIS showed the Stomach of a man which was in a condition of acute dilatation, and gave the following account of the case:—The patient, aged thirty-seven, was admitted into the Middlesex Hospital on suppurative of the ankle-joint. An operation having been determined on, on November 11th ether was given for about half a dozen respirations, and afterwards chloroform or about a quarter of an hour. For the following two days he vomited excessively a thin greenish fluid; the longest interval between the acts of vomiting was never more than one hour. He had taken a mixture of chloroform and ether on a former occasion without ill results. He had been prepared for the anæsthetic by being given a dose of house mixture, and an enema; a light breakfast was taken early. After the anæsthetic, orthopnoea became marked, the temperature fell below normal, the quantity of urine decreased, until towards the end none was passed; the pulse was weak and rapid, and the skin was cold. Death was due to exhaustion. At the necropsy, the stomach measured 7 × 12 × 4 inches, and reached almost to the symphysis pubis; it contained twenty-eight ounces of fluid. The coats of the stomach were thin, and contracted when cut; the kidneys were contracted and scarred on the surface, and one contained a cyst. In the upper lobe of each lung was a cavity, and the lungs contained miliary tubercle. The vomiting was unlike that seen after chloroform, and there was no intestinal obstruction. Mr. Morris referred to a few other cases of a similar kind on record, where excessive vomiting occurred in patients with a

similar condition of the kidneys; but all the other cases were much more chronic in their course, with the exception of three reported by Dr. Hilton Fagge. Mr. Morris was inclined to attribute the dilatation of the stomach to the large quantity of gastric fluid secreted, this over-secretion being brought about by nervous influence. He, therefore, thought that the term acute dilatation of the stomach was not a good one to describe the condition, and suggested the word *gastrorrhœa*. Cohnheim had suggested that in cholera there might be such an influx into the intestines from some nervous influences.—Dr. GOODHART gave a few notes of the post-mortems of five cases of acute dilatation of the stomach, which had occurred at Guy's Hospital since 1875, and which to some extent corroborated Mr. Morris's theory of the nerve origin. Of these cases, four out of the five involved the peritoneum, and the remaining one the sympathetic. Case 1 was a man, aged twenty-two, with strangulated inguinal hernia and suppurative peritonitis. Case 2. A female, aged forty-eight, with a growth in the neck pressing upon the veins, left vagus, and sympathetic. Case 3. A female, aged forty-nine, with ulcerating colon, acute enteritis, and thrombus of the superior mesenteric artery. Case 4. A female, aged twenty-four; amputation at hip-joint, suppuration in other joints, and caseous glands in the lumbar region. Case 5. A female, aged thirty-four; death nine days after ovariectomy; stomach symptoms began two days after operation. There was great flatulent distension on the fourth day; constant vomiting ensued on the sixth day. Post mortem there was very little peritonitis and thrombus in the iliac veins.—Dr. PYE-SMITH said that Dr. Lauder Brunton had preceded Cohnheim in the enunciation of the theory of the relation of nerve paralysis to the profuse evacuations in cholera; and Dr. Pye-Smith had read a paper on the subject, in conjunction with Dr. Brunton, at one of the meetings of the British Medical Association; he would be glad to know from Mr. Morris whether there had been any analysis of the vomited fluid.—Dr. MAHOMED wished to know the condition of the kidneys, as he had met with two cases of lardaceous disease of the kidneys, in which there was a large amount of fluid ejected from the stomach.—Dr. PAYNE alluded to two specimens in St. Thomas's Hospital Museum, where during life a diagnosis of intestinal obstruction had been made; but post mortem there was great distension of the intestine, but no obstruction; they seemed analogous to these cases of dilatation of the stomach. With regard to the influence of chloroform, while he thought that it might account for the symptoms by inducing paralysis of the muscular walls, it appeared to him very doubtful whether the distension could be produced by the quantity of fluid in the viscous.—Dr. WILKS remarked that while they had only a few fatal cases on record it was not improbable that there were less severe cases which recovered due to similar causes, and that the severe gastric symptoms which sometimes occurred in gouty people were possibly of this nature.—Mr. MORRIS, in reply to Dr. Mahomed, said that the kidneys were indurated and scarred, and one had a cyst, but that there was no lardaceous disease. He regretted that there had been no analysis of the fluid, but the true nature of the case had not been diagnosed. Alluding to the remarks of Dr. Payne, he did not suppose that the dilatation occurred until the stomach was worn out with the incessant vomiting, and so allowed of accumulation of the fluid.

Mr. MORRIS then showed photographs of a case of *Osteitis Deformans*. The disease had been present for about twelve years, and had begun in the left leg. The legs and thighs, the patella, the ribs, the vertebrae, the clavicles, and, to a slight extent, the cranial bones were affected. The lower extremities of the tibiae, the fibulae, the feet, and the lower jaw were not affected in this case. His general health was good, but he had a mitral murmur, and the urine contained less than the normal quantity of urea.—Mr. TREVES said that the case was a further illustration of two facts:—1. That the bones of the arms were usually free. 2. That all cases where the bones of the upper extremity, except the clavicle, were involved, occurred in women. The loss of stature might be accounted for partly by the curves of the spine, and partly by its subsidence in a vertical direction. Finally, Sir James Paget has ascribed the condition to an inflammatory affection of the bone, and, comparing it with other inflammations of bone, Mr. Treves said that in the case of a girl aged fifteen years, under his care with chronic periostitis from congenital syphilis, the deformity in the leg presented precisely similar

[DEC. 16, 1899.]

characters.—Mr. NOBLE SMITH asked if any treatment had been attempted; in all Sir James Paget's cases iodide of potassium had been given with either no effect, or a bad one; he had, therefore, in a case now under his care, attributed the disease to some defect of nutrition, and treatment in accordance with that view had benefited the patient. The deformities were exactly like Sir James Paget's description, and were largely due, he thought, to the weight of the body. There was a family history of gout, cancer, and phthisis; but the general health of the patient was good.—Dr. WILKS said that one of the first cases ever shown was a man under his own care, who had previously been under a great number of medical men, and had a pile of prescriptions from them, and the main ingredient was the same in all—namely, iodide of potassium. He thought it was a common error to suppose that iodide of potassium had any influence on fully-formed bone.

Dr. TURNER then showed a Congenitally Malformed Heart. The organ consisted of an auricle with two appendices, the left being small, and a ventricle with an auriculo-ventricular valve of tricuspid form. The auricle received the inferior vena cava, and a right and a left superior vena cava. The pulmonary veins communicated with the left superior vena cava. The opening of the coronary sinus was close to that of the inferior vena cava. There was a well-marked Eustachian valve, and a narrow crescentic membranous fold over the entrance to the left auricular appendix, the rudiment of an inter-auricular septum. The aorta arose from the front of the ventricle, and gave off the coronary arteries and the three vessels from the arch in the usual order, and supplied the pulmonary circulation through an open ductus arteriosus. The arch of the aorta was directed to the right over the root of the right lung. Behind the aorta was a fibrous cord passing to the pulmonary arterial vessels representing the closed pulmonary artery. There was what appeared to be a rudimentary left ventricle without any trace of a left auriculo-ventricular opening. The specimen was obtained from a male infant, aged fifteen months, who was brought to the out-patient department at the North-Eastern Hospital for Children for bronchitis. Only a slight degree of cyanosis was observed until shortly before it died. The child had been born at full time, and was well nourished, and seemed healthy then, but had not thrived. The cyanosis had not been observed by the friends. The mother had no illness during the pregnancy, and gave no history of rheumatism beyond slight rheumatic pains occasionally.

Mr. BARWELL then read an account of his case of so-called Rachitic Osteomalacia, with extreme Deformity. The patient was a female, aged seventeen years, who had been under Mr. Barwell's care for the last three years, and the deformity had improved very slightly. The patient comes from the potteries in Staffordshire, is of healthy parentage, and the brother is a tall, well-built man. Mentally she is juvenile rather than weak-minded, and is as yet non-pubic. Nearly every bone presents extreme deformity, but the humeri, right tibia, and left ulna are bent to most acute angles; in the ulna the olecranon is elongated and bent at a right angle to the shaft. She is quite unable to stand. The bones are remarkably brittle, though rather less so than they were, consequently she has fractured the bones of both upper and lower extremities several times. There is no beading of the ribs nor enlargement of the epiphyses. Mr. Barwell's experience led him to consider the bones to be of normal thickness, but soft from deficiency of lime salts, and he questioned whether these extreme deformities were ever produced by true rickets. Some years ago, in attempting to improve the deformity of the femur of a boy in a similar condition to this patient the chisel went through the bone with very slight resistance, and about five ounces of pure oil flowed out. Both these cases suffered from pains at the convex parts of the bones. Mr. Barwell thought that these extreme distortions arose from increase of the medulla, at the expense of the bone substance, the so-called excentric atrophy, while there was very little bone-earth deposited in the thin shell of bone round the medulla.

Dr. NORMAN MOORE described his specimen of Stricture of the Intestine at the Ileo-caecal Valve, from a man in whom colotomy had been performed in the right lumbar region. The wound showed no unhealthy suppuration. The intestines above and below contained a considerable quantity of soft fluid faeces, but were not greatly distended. The stomach was normal. The small intestine was dilated, oedematous, and reddened; three and a half inches above

the valve it showed extensive irregular ulceration, which extended all round; some of the ulcers seemed healing, and there were puckering as of healed ulcers. The ridge of the ileo-caecal valve was very low, and the orifice was so contracted as but just to admit a large probe. Below the valve, for three inches, there was a less degree of ulceration. The colotomy wound was two inches below the valve.

large intestine. No tubercle was discovered. The glands normal. Externally the intestine except that the lowest part of the iliac colon was adherent to the abdominal wall. The thickened above and below the stricture were found; the rectum and bones were normal. Microscopic examination of the stricture is associated with a new abundant round cells penetrating all intestinal wall. The patient was a man, years, who died under the care of St. Bartholomew's Hospital. An attack, of the bowels, began on October 1st, not having acted up to November 1st. Relief was done by Mr. Marsh. At the relief, but the next day a large quantity of stool passed through the wound. The patient died. A microscopic section of the tissue was exhibited.—Dr. NORMAN MOORE also showed a specimen of Malformation of the Right Auricle. It was from a woman aged thirty-three years. All the valves were hypertrophied and dilated. The mitral valve was thickened, and the aortic valve was slightly thickened. There was some thickening of the tricuspid valve. The edge of the tricuspid valve is slightly thickened. There was some thickening of the mitral orifice and a slight degree of the mitral orifice.

The left auricle is very capacious, and much thickened and puckered in several places. The fossa ovalis is complete, and the fossa ovalis stretches one inch into the auricle; it is a fossa ovalis and stretches from the septum near the orifice of the inferior vena cava to the posterior wall of the auricle. The valvula is of the usual form, and may be quite free from this projection. In the edge of the projection is a thickening one long, and the free edge is rounded and slightly the main part. The origin from the auricle is still. He had seen one other example of this probably developed in connexion with the Eustachian valve. Another specimen shown by him, with microscopical examination of the liver, belonging to a man, who died in St. Bartholomew's, under the care of Dr. Andrew, of tubercular pulmonary phthisis with of the larynx. The liver is studded throughout with numerous whitish growths, most of them a large pin-head. Microscopic sections show tubercles. Giant cells may be found in most of the cellular elements are not at all degenerated. Others caseation has taken place; all show a large amount of connective tissue. Virchow, Cornil and Rindfleisch describe tubercle as often found in the general tuberculosis of children; and Virchow that it more often occurs in the liver than in the lung; but cases in which the whole liver is affected at so late an age as forty-nine in phthisis, with tubercles in the lungs, are certainly rare in London. The fourth specimen was the Elbow Joint from a case of Scarlet Fever. The joint shows thickening of the synovial membrane, with roughness in two places and some adhesion. When opened it was full of pus. The joint of the right index-finger and the right elbow were similarly affected. No abscesses were found in the head. There was some pericarditis and general peritonitis. There were some minute growths on the mitral valve, and in the lower lobe of the left lung there was a small abscess. In each kidney was an infarction, and down so as to form a small abscess. The patient, a man, aged six years, who died in St. Bartholomew's Hospital, under the care of Dr. Gee. Another child of the family died of scarlet fever. This one was taken ill on Sept. 25th, and died on Oct. 10th she had rheumatic symptoms, which rapidly

ew worse. On admission, on Oct. 19th, both elbows were found to be much swollen. The temperature was 100° on admission, and twice rose to 104·9°. The child grew weaker, and died on Oct. 23rd. The case

of interest in its bearing on the question of the pyæmic or non-pyæmic nature of scarlatinal rheumatism. This case, in its anatomical features, was clearly pyæmic. Dr. MAHOMED protested against a case like this of pyæmic inflammation of a joint, after scarlet fever, being regarded as in any way of the same nature, or throwing light upon scarlatinal rheumatism. These pyæmic cases were very rare, while scarlatinal rheumatism was very common. In their clinical aspects they resembled acute rheumatism and yielded to salicylates; but, as a rule, they were of a milder type than ordinary acute rheumatism. There were some septicæmic cases, but they also were rare, and had no joint troubles; he thought that it was very misleading to represent scarlatinal rheumatism as not amenable to treatment.—Dr. WILKS asked if the pyæmia could be traced to any local cause, such as an abrasion of the throat. Dr. MOORE had examined carefully, but found no local abrasion, he had shown the case from a morbid anatomy point of view, and he had experienced some difficulty in drawing a line at the point where rheumatic affections end and pyæmic symptoms begin.—Dr. BARWELL said he had always assumed that absorption of morbid products, analogous to what occurs in gonorrhœal rheumatism, was the cause of the joint inflammation, and had always entertained the idea that scarlatinal rheumatism was not true rheumatism.

Dr. SOUTHEY brought the body of a child two and a half years old who had died with Symmetrical Gangrene. She was of healthy parentage, and had been previously quite healthy, except that two or three months ago she had a severe attack with some purpuric spots. On Friday, December 1st, she had a pain in the head; on the following morning she seemed quite well again, but in the afternoon complained that she had hurt her leg, but when her father asked her she said that it pained her, and he then noticed some lividity over the calf. Soon after, she was sick, febrile, and complained of headache; at six P.M. she was worse, and the lividity of the calves had extended both upwards and downwards; in the night the backs of the arms were observed to be affected, and at about six A.M. patches formed on the buttocks. She was admitted into St. Bartholomew's Hospital at noon of the 3rd inst., looking moribund; the pulse was rapid and feeble. The tibial arteries could not be felt; the lungs and heart were normal; at six p.m. she had taken some nourishment; she was ordered a warm bath and some nitro-glycerine; the cheeks were beginning to show a slightly livid redness. At seven P.M. convulsions came on and continued until she died at midnight, thirty-two hours after the first symptoms. Renaud had described similar cases, and Dr. Southey had met with two or three others; Dr. Moore had cut up the left femoral and tibial arteries, but no embolus or other obstruction could be found. The theory advanced has been that there is spasm of the arteries, and then migration of blood elements into the skin, or the gangrene was quite superficial.—Dr. NORMAN MOORE said that he had examined the blood microscopically, and that it was whitish comparatively, containing many fat globules, something like the so-called "raspberry-juice blood" found in some cases of diabetes.—Dr. WILKS mentioned a case of this kind in which hæmatinuria was present.—Dr. SOUTHEY had also observed intermittent hæmatinuria in a case with symmetrical gangrene of the fingers. In his present case only an ounce of urine could be obtained, and it contained some albumen.

Mr. EVE brought a recent specimen of Cancer of the Esophagus; leading from it were two fistulous passages into a cavity of the right lung, which had no definite wall. The patient had suffered from dysphagia for six months, and was in the hospital for only two days before death. Bougies were passed, and gave relief, but no attempt was made to administer food by the mouth. In the same patient an abnormal condition of the colon was found; from the cæcum the ascending colon passed down almost to the pubes, and then curved upwards towards the right kidney. He also showed the calvaria of a man who had died an hour and a half after a blow on the head; the skull was fractured, the fissure extending across the course of the middle meningeal artery, which lay in a very deep groove in the bone; the dura mater beneath this was separated from the bone by a large blood-clot.

Dr. LEES exhibited the Larynx of an infant, aged twelve

months, which had, during its whole life, manifested a peculiar noisy respiration. The condition found threw light upon a set of cases of rare occurrence, but of considerable interest. An infant, almost invariably of the female sex, suffers from the moment of its birth from a noisy inspiration, expiration being much less affected or entirely free, and the cry-sound being quite clear. The noise made during inspiration is often loud and harsh; it is of lower pitch than the crow of laryngismus. It continues, though it is not so loud, during sleep and after the administration of chloroform. There is usually some recession above the sternum, and slightly at the base of the thorax, but not much, and generally sufficient air enters the lungs. In some cases exacerbations have been brought on by exposure of the surface to cold (when the chest was stripped), by flatulence, and other causes; but as a rule the condition is fairly constant. Perfect recovery ordinarily occurs after the lapse of a year or more. In this case the child died of insidious diphtheria. About a month ago a laryngoscopic examination was made, and it was then seen that the epiglottis was folded on itself like a leaf on its mid-rib, the ary-epiglottic folds being thus brought close together, and the superior orifice of the larynx converted into a linear median slit of very small diameter. This condition was found post-mortem to be actually present, the ary-epiglottic folds being almost in contact. Above them, below the centre of the folded epiglottis, was an opening of the size of a pinhole, and between the arytoids a second opening a little larger. The trachea was lined with diphtheritic membrane. The peculiar breathing thus appears to be due to a congenital abnormality in the epiglottis. This was the fourth case which Dr. Lees had seen. Similar cases have been observed by Dr. Gee and by Dr. Barlow, but they have not yet been published, and Dr. Lees believed that this was the first post-mortem examination which had been obtained, and also the first time that the cause of the obstruction had been ascertained during life.

Dr. Finlay and Mr. Barker were then appointed auditors for the year, and the meeting adjourned.

## CLINICAL SOCIETY OF LONDON.

### *Cases of Intussusception treated by Abdominal Section.*

THE ordinary meeting of this Society was held on the 8th inst., J. Lister, Esq., F.R.S., President, in the chair. The evening was occupied by an interesting debate upon the subject of abdominal section for intussusception, introduced by Mr. Godlee in a paper on three cases in which that procedure was followed, one case being successful. The other papers on the agenda had in consequence to be postponed, but Dr. Coxwell exhibited his case of a child with symptoms resembling those of myxœdema. Dr. T. H. Green exhibited a well-marked case of pseudo-hypertrophic paralysis, the patient being a man twenty-four years of age, and the symptoms of the disease only having appeared one year previously.

Mr. GODLEE read a paper on three cases of Intussusception in Infants treated by Abdominal Section.—Case 1, an infant of nine months, was admitted into University College Hospital with well-marked symptoms of intussusception, from which it had been suffering for four days. The bowel protruded at the anus. The child was very ill and weak, and it was doubted whether it was justifiable to perform any operation. It was not thought wise to spend much time on attempts at inflation, and accordingly abdominal section was performed without much delay. Antiseptic precautions were adopted throughout, the child being as far as possible protected from the chilling influence of the spray by using as small a volume as possible, and wrapping up the greater part of the trunk and legs in cotton-wool. No great difficulty was experienced in finding the point of involution, nor in reducing the intussuscepted part. The wound was secured as in an ovariectomy, and a dressing of iodoform wool was applied and secured by a flannel roller. The temperature rose the day after the operation to 105°, but soon fell to about 100°. It was necessary to give small quantities of brandy after the operation, and for some few days minim doses of laudanum were given to check restlessness and a slight diarrhœa which ensued. A little suppuration occurred along the course of the sutures, but the wound healed well,

it is unjustifiable. So in intussusception, temporising measures, such as inflation, the longer such interference is postponed the success are lessened, and operation save life. And this must be the course pursued in spite of a few cases being spontaneously cured by sloughing of the intussuscepted gut; just as in hernia, operation has been refused, spontaneous place by a turn in bed or under the influence of a cathartic, and is believed if this principle were more of successes would be recorded. He was a facility with which Mr. Godlee effected withdrawing the bowel without requiring kneading. His failure in the third case, for the fact of the appearance of the caeci would generally imply that the had been fully reduced. — Mr. Howe congratulated Mr. Godlee on the success a success which taught two lessons — of infants for such an operation, mechanical treatment early applied, by degrees that children bore abdominal pressure. Mr. Bryant had pointed out that the operations for intussusception were pure had rightly compared the condition Opponents of the operation might argue few successes, the fact being that the which operation could be expected to succeed showed in how short a time inflammation could occur so as to prevent reduction; cases the strangulation did not seem to although in each case blood was passed, a very fact of hæmorrhage occurring showed Fagge had pointed out, that the circling going on in the partially strangulated period at which strangulation comes on. It is not the time that the intussusception period during which symptoms of strangulation present that is of importance. Thus he had of a child who had had intussusception strangulation for only twelve hours. In fatal cases the operation had been delayed, seeing the good results of abdominal operation with Mr. Bryant in urging early interference do not succeed, the operation should be performed. The severity of an operation is no good objection, if it be the only means likely to succeed, is extremely fatal, for, setting aside a few spontaneous cures, almost all die, and therefore he to be on the alert in such cases. Mr. Marshall advocating the procedure of reduction, Mr. Hutchinson as preferable to simple traction, agreed with Mr. Marshall on the minor duration of the intussusception itself as an interference; for during the past year he had his care three cases, in two of which recovery after inflation. In these cases symptoms had for from three to five days. The symptoms of, however, were not severe, there being very little of the abdomen, the patients suffering from little from twinging pains. In the two successful cases, reduction yielded to insufflation under chloroform; there were five and eight years of age respectively. The case was a younger child, who was in a more collapsed state, inflation reduced the size of the tumour considerably, passed from the left side of the abdomen to the right was given, but in a few hours the tumour returned to its size and position. Mr. Golding Bird saw the case after performed inflation, with the same result as before collapse ensued. After death examination showed incomplete reduction, which was completely effected by injecting water into the bowel, but not without effecting rent in the peritoneal coat. — Dr. MAHOMED mentioned a case of chronic intussusception lasting nine months, the nature of which was not clear, notwithstanding the nature of ing and passage of a portion of intestine. It occurred to him in that case whether it would not be justifiable to lay down on the bowel and remove it. He therefore suggested that excision of the intussuscepted bowel might be of value in cases which could not be reduced by other means. Mr. HOWSE said that the results of abdominal intussusception were not very encouraging. Since the case recorded by himself and Dr. Fagge, in the Trans. he had had four cases, in two of which the

the fact that the Commission has not yet received any information from the Government of the United Kingdom regarding the proposed changes to the law.

reption had protruded from the anus. In two of the cases operation was tried, but owing to their severity operation was to be performed. On each of the four cases he failed to effect the intussusception. In two he excised the ilio-cæcal valve, which remained unreduced. But the excision of a piece of intestine with the abdomen laid open was not easy, there being great risk of tearing the softened gut; and he suggested the use of a thin elastic sheeting to shut off the bottom of the cavity whilst excising. Another difficulty he met with was in bringing the divided ends of the bowel together, it being very difficult to draw them sufficiently tight. It might be well in cases where the intestine protrudes through the anus to adopt another measure, similar to that followed by an Italian surgeon, who, mistaking the condition of one of simple prolapse, drew down the tumour and cut it off easily away; the case did well. Some such procedure as this might succeed, for it would be comparatively easy to cut off the intestinal mass, and yet the peritoneal cavity would be shut off by the adhesions in the intussusception.—Dr. AHOMED added that he should have referred to Mr. Bryant's successful cases of excision of portions of diseased intestine.—Dr. ANDREW CLARK commended Mr. Godlee for his modest record, and wished to ask whether the effects of such operations on young children had been noted, especially as regards variations in the temperature. If observations on temperature were made during such operations, we might the better understand the various factors engaged in the production of temperature.—Mr. HAWARD said that no doubt it was very desirable to make the distinction, if possible, between those cases in which the bowel is merely invaginated and those in which it is strangulated. The acuteness of the symptoms was some guide, but it cannot be altogether depended on. There was lately under the care of Dr. Cavafy and himself a child, seventeen months old, whose attack had commenced with vomiting five days before; the bowels were twice opened after the first symptoms, and blood had been passed for two days. On admission the invaginated bowel could be felt per rectum. Ether was given, and injection with inversion failing to effect reduction, the abdomen was opened. Although acute symptoms had been present for five days there was no difficulty in withdrawing the invagination (consisting of ileo-cæcal valve and ileum) by slight traction and support from above. The main difficulties now arose. The bowels, being greatly distended with gas, could not be prevented from protruding through the abdominal wound. Inversion and gentle manipulation failed to replace them; nor did simple punctures to let out the gas suffice. Finally, the distended coils had to be tapped with a trocar, liberating gas and fluid faeces, before the intestines could be got back. This same difficulty has occurred to others in abdominal section for intestinal obstruction. The child died a few hours after the operation, with commencing peritonitis, which Mr. Haward thought was due to the above protracted difficulty.—Mr. BECK had done this operation six years ago, in a child under one year old, who survived it for thirty-six hours. There was some difficulty in reducing the intestine, which he had to draw out on to the abdominal wall; and he tried to reduce it by both pushing and pulling on the intussusception. During these measures fissures appeared on the surface of the vulvulus, and the child ceased to breathe, but was restored by artificial respiration.—Mr. PEPPER remembered the case referred to by Mr. Beck, which raised in his mind doubts as to the propriety of such operations. Since then he had seen one operated on by Mr. Pye, in which the peritoneal coats also split. He pointed out that Mr. Pollock, writing in "Holmes' System of Surgery," says that a very considerable number got well spontaneously, and, if so, it became a question whether it is wise to operate at all.—Dr. BUZZARD pointed out that a case of intussusception was not to be placed in the same category as ovarian disease, where there is no natural attempt at recovery; for in intussusception from the time inflammation (and therefore obstruction) sets in the natural process towards recovery is commenced, ulceration ultimately succeeding in cutting off the intussuscepted part. In every case there is this natural tendency to recovery, but in the majority the patient dies in the process. At the same time he did not wish to discourage the operation, which was often the only chance.—Dr. GLOVER asked whether belladonna might not do good, and related the case of a child who had obstruction for ten days (not, however, due to intussusception), in which no relief had been obtained under opium and enemata, and abdominal section was on the point of being performed, when

belladonna was given—the extract in quarter of a grain dose, every four hours; and after the fifth dose the bowels were freely relieved.—The PRESIDENT said that the Society was to be congratulated upon the valuable discussion and the paper that had given rise to it. Mr. Howse's suggestion, although startling in its novelty, deserved careful consideration, for it was an imitation of the natural process of cure referred to by Dr. Buzzard. The peritonitis in Mr. Godlee's second case was, he felt no doubt, due to the state of the bowel, just as in peritonitis following strangulated hernia, and he did not think it attributable to the spray. In abdominal surgery it would seem that antiseptic precautions are less important than in surgery generally; but it must be remembered that those who say they operate without such precautions do really follow the practice, in scrupulously observing cleanliness in boiling or steeping sponges and instruments, &c., although they do not use the spray. Mr. Godlee took antiseptic precautions, but it was very unlikely that the spray was the cause of the peritonitis, and nothing more likely than that the condition of the bowel determined it.—Mr. GODLEE, in reply, said that no doubt in that case of peritonitis the strangulation had lasted longer than in the others. He believed there were very few cases on record where the bowel had separated by sloughing under the age of one year, and inflation was less likely to be successful in such young children; besides, it produced very great exhaustion. Dr. Taylor's cases were older, and the youngest died. He was encouraged by Mr. Bryant's and Mr. Marsh's remarks, and concurred as to the importance of diagnosing the fact of strangulation. It was difficult to know when strangulation occurs, for bloody mucus was passed without there being strangulation, and griping pains might even occur without it. The plan he adopted in the reduction was unrolling the ensheathing portion from the ensheathed, using very little traction; but these cases proved exceptionally easy to reduce. The temperature rose rapidly in the second case to 103° or 104° after the operation. There was a difficulty in returning the intestine into the abdomen, especially in the second case. He added that, in 1877, Dr. Sands, of New York, published a table giving seven successful cases of this operation out of twenty-one cases.

## MEDICAL SOCIETY OF LONDON.

### *The Treatment of Syphilis.—The Difficulty of Diagnosing true Syphilis in Females.*

A MEETING of this Society was held on the 27th ult., Mr. F. Mason, President, in the chair.

Dr. DRYSDALE read a paper on the Treatment of Syphilis. He first alluded to the growing belief in a specific germ in syphilis, and exhibited a specimen sent him by Dr. Ebland of Stockholm, showing the fungus from gonorrhœal discharge. The treatment of syphilis was still undetermined. Dr. Fournier advises the use of interrupted courses of mercury for two years and ten months, in daily doses of about one grain and a half of the proto-iodide; Dr. Keyes of New York recommends a daily dose of about half a grain of the same salt, given continuously, perhaps for three or four years; whilst in London there was scarcely any regular treatment of the disease by prolonged courses of mercury, and in Edinburgh some practitioners give no mercury at all. Syphilis was introduced into Europe in 1492, and first treated by inunction in 1497. Paracelsus first gave mercury internally in 1570; and until 1812, in this country, there could be little doubt that mercury had poisoned fatally perhaps as many patients as had been killed by syphilis, which until 1836, when Wallace of Dublin published in THE LANCET his account of the treatment of tertiary syphilis by iodide of potassium, must have been a terrible disease. It was now known that syphilis varied very much in intensity, a certain number of cases getting well without any local measures. He himself had treated syphilis with iodide of potassium only; but Fournier and Hutchinson were so positive as to the power of mercury to prevent tertiary symptoms that he had begun to regard mercury as a possible germicide, and for some years past had given it continuously for months to all patients with well-marked sore or with secondary symptoms. He gives one-sixth of a grain of the proto-iodide or one grain of mercury with chalk, and since he has used this treatment he has not met with any salivation, whilst at the same time, so far as he knew, the patients have had a

[DEC. 16, 1882.]

complete immunity from tertiary symptoms. When iritis supervened or severe rheumatic pains with headache, he increased the dose and prescribed inunction. He advocated the early commencement of mercurial treatment and its prolonged use on the ground of its antagonism to the syphilitic virus.

Dr. ROUTH read a paper on the Difficulty of Diagnosing True Syphilis in Women, and the Nature of its Contagion, with the especial view of combating the Contagious Diseases Acts. He particularly dwelt upon the insignificance of the initial lesions in women leading to their being overlooked on examination, and spoke of the extreme virulence of the syphilitic poison. He then remarked that it was proved (1) that a female could contaminate by her secretions alone, quoting several French and English authorities, and that Fournier extended this contagious power to three or four years; (2) or by mediate contagion owing to promiscuous intercourse; (3) by women who had been cured of syphilis so as to be incapable of re-inoculation and yet fertile sources of infection. He maintained that the contagion of syphilis was intensified in virulence wherever brothels were tolerated, as illustrated by reference to reports from France and Brussels; and that the danger of licensed houses was increased by the inadequacy of examinations. He also showed from the English data of the Contagious Diseases Acts that true syphilis was more severe in the protected than in the unprotected districts, the number of constantly sick being greater, and that even Mr. Lawson admitted the chance of a soldier contracting syphilis in the former as compared to the latter is as 36 to 33; and that for the last two years from the Army Reports syphilis had increased in the former 57 per cent., in the latter 45 per cent.—Dr. DRYSDALE confirmed the statement as to the increase in the prevalence of soft sores in London and Paris of late years; and also that syphilis had increased in Paris, which he attributed to the clandestinity caused by the police regulations.—Dr. F. SIMMS agreed with Dr. Drysdale's remark, and added that the presence of a soft sore was an unsafe reason for inferring the absence of syphilis. It was hard to diagnose a primary sore with certainty.—Mr. H. LEE suggested that the Society should undertake the preparation of a scientific digest of the evidence respecting the working of the Acts. Before the passing of the Acts syphilis and gonorrhœa were decreasing, but now both are on the increase. He corroborated Dr. Routh on the extreme difficulty of diagnosing primary syphilis in the female, and the same with respect to gonorrhœa. He had produced the characteristic pustule by inoculating the discharge from the healthy vaginal membrane of a syphilitic woman. The army returns were defective in not giving the cases of secondary syphilis or in distinguishing soft and hard chancres. In women the diagnosis was more difficult by the absence of the characteristic symptom found in men—the enlargement of the inguinal glands. As women only were examined under the Acts, the difficulty in diagnosis seemed to cut at the root of the scientific value of the statistics. It was a question whether one-tenth of the money that these Acts cost to execute, spent on sanitary objects in barracks, would not do far more than the execution of the Acts.—Mr. ST. GEORGE MIVART drew a distinction between the French system, which had broken down from the brutality of the police, and the English; and Dr. Routh's arguments were mainly drawn from the former. The most common source of infection he believed to be mucous tubercle, and not primary sore.—Mr. EDMUND OWEN had found that soft sores were apt to become indurated, and to be followed by secondaries, whilst infection not uncommonly was the sequel to a sore which never bore typical induration, and he believed beyond doubt in the unity of syphilitic virus. He protested against Dr. Routh's conclusion that the working of the Contagious Diseases Acts increased vice and propagated disease. The evidence given before the Select Committee had led its members to form the opposite conclusion.—Dr. DRYSDALE and Dr. ROUTH briefly replied.

#### ACADEMY OF MEDICINE IN IRELAND.

A MEETING of the Surgical Section took place on the 8th inst., Mr. J. K. Barton, President, in the chair. In the library a man who had been trephined for abscess on the brain was exhibited by Mr. Kilgariff, and various specimens by card by Messrs. Franks, Croly, A. Benson, Stokes,

Wheeler, and Abraham. Mr. Wheeler's included an interesting cast of dislocation of the wrist, caused by the contracting cicatrix of a burn, and Mr. Abraham showed the sputum of bronchitis and phthisis, contrasted in reference to the bacilli. Mr. Barton then gave the inaugural address as president of the section, and referred to the Surgical Society which had lasted for the past fifty years, and which had become merged in the Academy of Medicine. He compared the surgical clinical instruction in the Dublin with the continental system, and mentioned some of the most difficult problems of surgery which he thought would be of advantage to read a paper on the case of trephining of Trim, on a case of nephrectomy by Mr. K. The patient, a girl, was admitted into and died in forty hours after the operation. On removal the kidney weighed ounces and contained an abscess from which pus exuded. The case was evidently a tubercular disease of the organ. Mr. K. dissecting aneurism of the aorta, which was considered should have been kept in the Section, and the proceedings terminated.

#### Reviews and Notices

*Animal Plagues; their History, Nature, and Prevention.*  
By GEORGE FLEMING, F.R.C.V.  
Vol. 2. London: Baillière, Tindall,

PREVIOUSLY to the outbreak of cattle plague in this country, the history of animal plagues had attracted much attention, and when the ravages of the disease were so extensive, and the attention of veterinarians and stock-owners into a state of activity, it did not seem to occur to the public that the disease was not a new one, and that it was lying ready to be presented to the world. It was a new one, and for some time England presented a spectacle of a people seeking with much anxiety for circuitous paths information which was lying at least to eye, in the veterinary literature of Austria. Had the history of the disease been familiar to English stock-owners in 1800, agriculture would have been immense, and there was no accessible English work which contained useful information on the subject, and our authors who could have enlightened them, and who could have depreciated the benefits of foreign impost.

It is difficult to convey an adequate idea of the objects of the work on Animal Plagues without further into details than our space will permit, but there is no hesitation in asserting that the two volumes on Plagues, added to the companion volumes on Sanitary Science and Police, and Rabies and Hygiene, are evidence of the remarkable industry by which their author has surmounted difficulties of no ordinary character.

The volume now before us is, we are told, the writer's labours in this direction. In the first volume, which was published in 1871, the history of epizootics incidentally of epidemics, included the period from B.C. to A.D. 1800. In the present volume the history is continued from 1800 to 1844, after which date the writer is not his present intention to carry on the record, as from that time "Veterinary literature became largely developed, and there is no difficulty in tracing the origin and extension of the more remarkable at least of the animal plagues which visited the civilised world." Nevertheless to present in one view a record of the principal epizootics which have appeared since 1844 would be a satisfactory conclusion to the work, and although it might present no difficulty to Mr. Fleming, we question if any of his professional brethren are likely to attempt it.

carrying out his self-imposed task, the author has adopted the system of chronological reference, instead of attempting a complete history of each form of disease. Commencing in the first volume with the murrains of Egypt, in the first chapter he gives an account, necessarily a concise one, of the plagues which the earliest historians have alluded to between 1490 B.C. and 400 A.D. Then, in the next chapter, in the space of some ninety pages, is compressed the history of eleven hundred years—from A.D. 400 to A.D. 1500—an unprofitable period, as the writer describes it. Coming gradually to more modern times the accounts of zootics in various parts of the world become the more interesting, for the reason that it is possible to connect the animal plagues of a former period with those which are familiar to this generation of stock-owners. As a concise record of the rise and progress of animal plagues from the earliest times, the value of the work to the veterinarian cannot be over-stated, and it may not be out of place to suggest that the agriculturist will find in it matter well worthy of his attention. In the last twenty years the stern logic of facts has convinced farmers that the ravages of the most deadly diseases of the lower animals are not, in their estimate, to be lightly estimated; and they are not now supposed to laugh, as they did in 1862, at the idea of legislating for the movement of animals merely because they had few blisters on their tongues and feet. Mr. Fleming's work is likely to find readers among a class to whom a few years ago its teachings would have seemed to possess no meaning.

*The Practical Working of Direct Vaccination from the Calf.*  
By BENJAMIN BROWNING, M.D. Reprinted from the Transactions of the Society of Medical Officers of Health.

IF Dr. Browning had contented himself with giving some account of the methods to which he had resorted for the vaccination of calves, his pamphlet would have merited more approval than we are now able to accord to it. The earlier pages are devoted to an attempt to show that calf lymph should be employed to the exclusion of humanised lymph. A few words will suffice to demonstrate the error into which he has fallen. He begins by showing that absolute immunity from small-pox is not always to be procured by the use of humanised lymph, and he then makes the bold assertion, that animal lymph "never fails in preventing small-pox." This last statement appears to be based upon the fact that 150 persons vaccinated by him with calf lymph, though living in infected localities, had not subsequently suffered from small-pox. As matter of fact, there is no definite evidence of the amount of protection relatively afforded by humanised and animal lymph, but the history of small-pox hospitals gives ample proof that those exposed to the disease can be efficiently protected by the use of humanised lymph. Again, Dr. Browning states that the success attained in the use of the lymph which he cultivated was 97·13 per cent., but no information is given whether he refers to the number of individuals vaccinated, or to the number of insertions made; probably the former is intended, but there is again no evidence to show what he means by success, or whether he applies this word to cases in which vesicles are developed on only a proportion of the places of insertion. That good results are attained by direct vaccination from the calf there is no doubt, and the report which we recently published on the Animal Vaccine Establishment of the Local Government Board is sufficient evidence on this point; but Dr. Browning's pamphlet is calculated to give rise to the erroneous impression that the use of stored animal lymph is to be entirely trusted to, a belief which should not be encouraged.

We feel, however, with Dr. Browning, that there is ample room for the development of calf vaccination, and although

we cannot agree with all the observations which he makes, with reference to the methods to be adopted, some are deserving of attention.

## ORCHITIS IN TYPHOID FEVER.

*To the Editor of THE LANCET.*

SIR,—With reference to the sub-leader on this head in your issue of the 9th inst., perhaps the following notes may prove interesting.

A young officer in the Dublin garrison contracted enteric fever in the Linen Hall Barracks, and went through a well-marked and severe attack in the infectious diseases hospital under my charge. The temperature was high, at one time rising to 105°, and from first to last the duration of the fever was twenty-eight days before the normal point was reached. After about ten days' convalescence the patient was moved into lodgings, and kept in the recumbent position. Particular instructions were given regarding the food, and close attention was paid to the state of the bowels, which for the latter part of the attack had been constipated. After a few days he began to sit up in an arm-chair, and was rapidly recovering, when suddenly he experienced an attack of severe pain in the right iliac fossa, and on being sent for I found him with a coated tongue, a temperature (evening) of 102°, a pulse of 120, and a decided tenderness over a considerable portion of the abdomen. On inquiry I found his bowels had become constipated, having had no motion for thirty-six hours, and it further transpired that he had been sucking grapes and had swallowed some of the seeds. He complained also of pain in the right testicle, but there was no orchitis. I ordered hot fomentations to the abdomen, half an ounce of castor oil in warm milk, and a large enema of warm water. Next day he was worse. Morning temperature 103°, evening 104°; tongue very foul; pulse 120; severe pain and tenderness over abdomen, with orchitis of right testicle. Some relief had followed the oil and enema, but there was evidently more to come away. Another large enema was given, which acted well on the bowels. Hot fomentations were kept to the abdomen and scrotum, and one grain of calomel and half a grain of opium were given every fourth hour. On the following day the temperature fell to 99°, the pain and tenderness in the abdomen had disappeared, but the testicle remained swollen and tender. The scrotum was not inflamed. The epididymis was not involved, but the right cord was painful on pressure. From this time the case did well, and the young man is now quite convalescent.

I am, Sir, yours truly,

J. B. HAMILTON, M.D.,  
Surgeon-Major.

Dublin, Dec. 9th, 1882.

## DEATH IN PRISON.

*To the Editor of THE LANCET.*

SIR,—On reading your remarks upon a recent death in Huntingdon goal in THE LANCET of December 2nd, the evidence of the governor of the prison, that "there are no arrangements under which, in the event of any sudden illness or other emergency, and the surgeon or assistant-surgeon being absent from the town, I can call in another medical man to attend a prisoner," struck me as very surprising, and as proving to how great an extent red-tape may fetter and cramp the official mind. The medical officer of a local prison can, with the approval of the commissioners, appoint a substitute, who, in cases of emergency, and in the absence of the medical officer, may visit the prison. In the event of the medical officer and his substitute being both of them engaged or absent, it is still possible for the governor of a prison to call in the nearest available medical man. In proof of this I may state that, three or four years ago, one of the warders of Her Majesty's prison at Deverges was murderously assaulted, and severely wounded by a prisoner with a knife, which he used for mat-making. The governor of the prison, very properly seeing the urgent nature of the case, at once despatched a messenger for the nearest surgeon, as well as for me who lived at a greater distance. We arrived together, but I was only too glad to have the assistance of my friend in attending to the wounded man. In this case the commissioners at once allowed my friend a fee for his services, thereby sanctioning the action of the governor in sending for the nearest help.—Yours, &c.,

EDWARD CLAPHAM,

Wimbledon, Dec. 11th, 1882. Late Med. Officer H.M. Prison, Deverges.

# THE LANCET.

LONDON: SATURDAY, DECEMBER 16, 1882.

## Sir Thomas Watson, Bart.

FULL of years and of honours, the greatest English physician of the present century has at length gone to his rest. We have elsewhere given some details of Sir THOMAS WATSON'S distinguished career, and we have traced his progress from the Grammar School at Bury St. Edmunds to the unquestioned headship of the medical profession, a position which for many years he occupied with singular honour and dignity. As he was honoured by being so highly placed amongst his professional brethren, so his exaltation may be said to have reflected honour upon the profession, whose members so highly and so universally appreciated the high qualities of their revered head.

The last occasion on which Sir THOMAS WATSON attended a meeting of the Fellows of the College of Physicians was in the spring of the present year, when Sir WILLIAM JENNER was for the second time elected President. In the absence of the senior censor, the senior Fellow present was called upon, in the usual form, to deliver to the re-elected President the insignia of his office and to administer the formal oath. When Sir THOMAS WATSON got up to walk towards the President's chair, the whole of the assembled Fellows rose as one man to show their respect and affection for their venerable ex-President. The respectful feeling which was then so touchingly and spontaneously displayed by the assembled Fellows of the College of Physicians is shared by the entire profession, who will feel as a personal loss and sorrow the removal of one whom they have so long been accustomed to regard as their most distinguished member. What, then, are the qualities which have gained for this great physician the respect and affection of all who have had the privilege and the happiness of knowing him? It is the rare and happy combination and balance of great intellect with the highest moral qualities which constitute the truly wise and good man. In this sense an eminent living physician has spoken of Sir THOMAS WATSON as the wisest man whom he had ever known; and a near relative describes him to have been the most unselfish of men. His own lectures and public addresses may be looked upon as giving the best and fullest illustration of the illustrious physician's mind and character. What student or practitioner of medicine can read thoughtfully that well-known and often-quoted introductory lecture in which, in terms of solemn and lofty eloquence, are set forth the privileges and responsibilities of those who enter the profession of medicine, without being led to form a higher estimate of his calling? without being inspired by the desire to act up to those lofty principles which the earnest teacher endeavours to infuse into his pupils? And that he taught no less by example than by precept is known and gratefully acknowledged by thousands who have had the privilege of his acquaintance. He was himself a living impersonation of the principles which he so eloquently expounded in his lectures. And, withal, he was modest and unassuming, as becomes a truly great and wise man.

THE theatre of the Royal College of Surgeons was crowded literally to overflowing, on Wednesday afternoon, when Sir JAMES PAGET delivered the first Bradshawe Lecture. It was mentioned last week that this lecture had been instituted by the widow of the late Mr. WILLIAM WOOD BRADSHAW, of Reading and Andover, who bequeathed £1000 to both the Royal Colleges with a similar object—namely, that a lecture might be delivered annually at each of these institutions to perpetuate the memory of her husband, it being stipulated that the subject should bear upon some question of medicine or surgery, but beyond this a very wide latitude being left to the lecturer. It is needless to say that the audience was not disappointed. It is impossible for Sir JAMES PAGET to treat of any subject without adding to it an interest and grace which are all his own, while his fluency and elegance of diction effectually prevent that irksome feeling of somnolence that afternoon lectures at the College of Surgeons are apt to induce in the most attentive.

The lecture was "On some Rare and New Diseases." Sir JAMES PAGET did not, however, enter into a description of the natural history of any one of the diseases to which he alluded, but after enumerating a few of those to which attention had been particularly directed, such as exostosis, deformans, the joint disease of locomotor ataxia, and others, he launched into the broader questions of whether or not these are actually new diseases? and, if so, how do they come into existence? Not only is this subject of the greatest possible interest in itself, but it supplies the lecturer with an excellent text on which to point to the methods of observation both of the common and of the rarer forms of disease. Let us take as examples some of the epigrammatic sentences, many of which will remain in the lecture, and which will doubtless remain in the recollection of those who heard those who may read his words. "Why are things new?" is a question we are told we should be in the habit of asking ourselves when brought face to face with cases presenting any unusual or interesting anomalies; we are not to treat such cases aside simply as anomalies or peculiarities, but therefore of but little interest, but to endeavour, if possible, the cause of their occurrence, to find the clue to the development of such new morbid conditions as those to which reference has been made. In the case, for example, with diseases as with family likenesses, the exact likeness is never transmitted from parent to child, so the tendency to disease is never inherited in precisely the same way, and thus modifications are introduced which gradually become solidified into a type? And if this be the case, in what manner does hereditary transmission modify the type of diseases? For instance, are the new forms which we occasionally observe hybrids, which have no power of transmitting themselves as such; or mongrels which breed more or less true; or are they, again, simply more morbid conditions existing as it were side by side with the type? On the other hand, should they be looked upon more as the result of combinations? "Collect bad specimens," says Sir JAMES PAGET, speaking from the point of view of research, has all his life had the interest and utility of morbid anatomy at heart. It is not by multiplying typical examples that a advance in discovery is to be made, but rather by the careful record and preservation of those which we do not understand.

as JOHN HUNTER's specimens of gumma in the gæmæus, and typhoid ulcers in the intestines. Speaking of the specimens, Sir JAMES PAGET says, "It would be very odd if some one would collect hundreds or even thousands of them and arrange them, even though it were only under headings as I have just indicated. But even as they singly and in disorder, let me say that we ought not to throw them aside with idle thoughts about 'curiosities' and 'trifles.' Not one of them is without a meaning; not one might be the beginning of excellent knowledge if only it could answer the question, Why is this rare? or, being rare, why did it in this instance happen?"

Sir JAMES PAGET expressed the belief that some diseases are really been developed in comparatively recent times, and are becoming more common as the result of hereditary transmission; for, as he pertinently observed, it is scarcely conceivable that marked and chronic deformities like those produced by osteitis deformans or Charcot's joint disease could have escaped the observation of such careful observers and indefatigable collectors as "HUNTER, HOWSHIP, LANGKAF, COOPER, STANLEY, and others, who collected not merely illustrations of disease well known to them, but whatever was curious whether it was known to them or not;" and yet there are no examples except of ancient date in any of our museums. At the same time he pointed out that many so-called new diseases, such as Bright's or Addison's, are really old at the time of their discovery, and are only recognised by the light of increasing pathological knowledge. And it was also shown that the study of the varieties of well-marked species of disease is not merely of pathological but of the greatest practical interest. Many drugs which are of undoubted value in certain examples of a particular malady, such as bromide of potassium in epilepsy or salicatum in chronic rheumatic arthritis, fall into disrepute, because in a certain other number of cases they appear to be absolutely useless; but "that which some call the fallacy of therapeutics is generally the fallacy of diagnosis. We need not only the diagnosis between diseases essentially different, but that between the different and varying forms of each of those which we call by a generic name; and, beyond this, we need a more exact power of what may be called analytic diagnosis; for there are few simple cases, and in those which are not simple we need to be able to discern all the components, and the proportions in which they are mingled or combined. Better treatment will follow better diagnosis, and better diagnosis will certainly follow a more exact pathology."

Everyone will agree with Sir JAMES PAGET in the praise he bestowed on those who have devoted so much time and labour on the perfecting of the Hunterian Museum, amongst whom none perhaps is more deserving than himself; and all will join with him in urging surgeons, wherever they may be, to do their part in helping to make this national collection perfect by sending up their rare specimens when occasion offers.

We have only to add that this the first "Bradshawe Lecture" has thus proved a most interesting and instructive occasion, and one not soon to be forgotten; and if succeeding lectures should even rival the first in interest, we may fairly assert that the name of this "home-loving and studious man, who diligently cultivated his mind in both literature

and science," as well as that of his "generous widow," will not only be handed down in good repute to posterity, but will be remembered from year to year as marking one of the red-letter days in the surgical calendar.

MANY of our readers must have been amused and somewhat puzzled by the lecture on Fever published in our last two numbers by the able and accomplished lecturer on Medicine at an important metropolitan medical school. That the lecturer abounded in witty sayings and in original exposition is to be taken for granted when one knows its source, and that it was unsparing and sarcastic in its criticisms is to be expected also, for Dr. MOXON is nothing if not critical. No doubt it is a good thing to get students to think for themselves, but subtle reasonings and semi-serious digressions are apt to bewilder them. In spite of such redeeming features as the urgent advice upon personal clinical observation and the value of first-hand knowledge, as well as its clear discrimination of the varieties of fever, the lecture as a whole seems to us somewhat out of place. No doubt Dr. MOXON's great dread lest we should be led away by mere words from the recognition of actual facts made him use his opportunity to demonstrate the fallacies of attempts to define fever, and a like sense of truth impelled him to confess that of the real nature of fever we know nothing, but know only our false mental conception of it; whilst it led also to his onslaught upon the rapidly growing tendency to find in the germ theory a sufficient explanation of the febrile process. That is why, probably, his lecture was so iconoclastic, and unsparing too in its iconoclasm, with but little proffered in exchange beyond an hypothesis as to the nature of fever, which was quite as chimerical as he believes the alternative theory to be.

Although one may disapprove of this lecture as a model of instruction, and dissent from its conclusions, yet one is not the less compelled to admire the freedom with which the lecturer spoke, or to admit the truth of many of his strictures. It seemed a little unfair of him at the outset to make so much of a single sentence as embracing a definition of fever, but doubtless he could not resist the temptation of demonstrating the logical fallacy involved in that statement; still he might have quoted the context where the writer in question guards himself against too "abstract" an idea of fever by enunciating its essential phenomena. Everyone will admit that a definition is one of the most difficult things in medicine, because of the imperfection of our present knowledge, and of all subjects that of "fever" is perhaps the most difficult to define. Even Dr. MOXON attempts a definition later on in his lecture, and exception might be taken to his statement that fever consists in a body temperature above 100°, since many would be satisfied with a lower criterion, which should yet be above the limit of normal variation in health. Dr. MOXON is very severe upon scientific teaching, or perhaps we should say upon the supremacy of all science in education to the detriment of facts of practical utility, and he charges the physiologists with the error of extending their sphere of knowledge in directions which promise but few practical results. The passages in which he touches on these subjects have a vein of truth running through them, so that one may pardon the digression which they involve from his proper theme.

The word "principle" started this digression, and Dr. MOXON seems to think aloud as he passes away from his subject down this and that bypath in a manner which must have been, at least, most entertaining to his hearers.

At length he returns to his main thesis, and, discussing the meaning of the word "kind" as applied to fever, he no doubt truly says that by "kind" we mean simply the existence of differences we are unable to explain; although in the case of living beings we are able to base distinctions upon the surer ground of the power of reproduction "after their kind." This power of reproduction is exemplified also in the specific fevers, and is considered a more reliable basis of distinction than the anatomical lesions, which Dr. MOXON regards almost as coincident rather than essential parts of the fever. His table of classification of fevers was intended to show the other and wider relations than those of species among fevers, and was drawn up much on the plan of the zoologist in dealing with groups of animals. In all this Dr. MOXON is easily followed, and is in the main right, but the statements which are the most original, and which are probably intended to excite opposition, are those which conclude the lecture—we mean his attack upon the germ theory of fevers.

Here, however, he is not content with mere iconoclasm, but by a series of ingenious arguments erects what one may call a sperm theory or a sperm and germ theory, as distinct from the fermentation or parasitic germ theory of fevers. Comparing the course of a fever in its varying episodes and inevitable termination to the life of the body itself, Dr. MOXON imagines that the micro-organisms of which we hear so much, and of which he takes the spirillum of relapsing fever as the type, are really portions of texture (we use his own phrases) cast off from one human body which can fertilise germ tissue in the infected body and start the process. Somewhat fancifully, it seems to us, he speaks of life itself being a protracted infection of the germ by the sperm, the living body remaining during its life germinal to other infections when suitable spermatogenic elements come into contact. In other words, there are textures in our bodies ready prepared for infection by fever-sperm cast off from other bodies, a notion not a whit less fanciful than the idea of a special pabulum for germs that come from without and are strictly parasitic. Moreover, clever at detecting fallacies in others, he seems to occasionally fall into error himself, since it was at least very unguarded of him to speak so contemptuously of the "bits of protoplasm" called bacteria, as if those believed to be characteristic of disease were identical with those which are met with in the presence of decay and putrefaction, and required similar nutriment and conditions for their development; and he does not mention that some hold it proved that these organisms are carriers of contagion, and are not the contagion itself; whilst he is actually inaccurate in the analogy he draws from the *filaria sanguinis hominis*. In the first place, as Dr. MANSON showed, the periodical entrance of that parasite into the blood-stream is associated with a rise in temperature, and, secondly, there is nothing in common, either as to origin, nature, or (probably) effect, between a nematoid larva and the protophytic or protozoic organisms which occur in the blood and tissues of certain specific diseases. Dr. MOXON does not hesitate,

moreover, to question the inferences derived from what are known as cultivation experiments and inoculations, and in a sentence ruthlessly dismisses the results of the patient and laborious research of PASTEUR, KOCH, and their followers, as being not proved, because the actual process of development of any single organism is not made manifest. Were the lecture not addressed to students, we should have thought Dr. MOXON was really not serious in making such objections; but if we must take him seriously, we would equally claim to discard his "alternative" unless he shows us in actual process the impregnation of assumed "virgin" tissue by the spermatogenic element, and until his theory receives so substantial a support as we see no reason to impugn the value of cultivation experiments, or to regard them as other than one of the supports in favour of the germ theory.

THE Criminal Lunacy (Departmental) Commission reported adversely to the almost universal protest of the medical superintendents against the practice of removing lunatics direct from prisons to county asylums. This, indeed, might have been anticipated, looking to the constitution of the Commission, and the manner in which it was about the business in hand. The Report opens with a characteristic exercise in hair-splitting as to the meaning of the term "criminal lunatic"; highly interesting, decidedly in the departmental, forensic, and statistical mind, but having nothing whatever to do with the practical question with which a considerable section of the medical profession has been for a long time past deeply concerned. Dr. EDGAR SPEAR, who, as our readers are aware, recently retired from the medical superintendency of the male division at Colney Hatch Asylum, after twenty years' distinguished service, put the main issue before the Commission thus—

"It is a grievance that the man or the woman known to be of a criminal type and class should be admitted into a county asylum, where there are, as I said before, a large number of very well educated people—people whose antecedents have been those of great respectability, and who are naturally very sensitive on a point of that kind. There is no doubt that they do feel it. A criminal is known to be a criminal, and is spotted as such, and he exercises a very baneful and prejudicial influence upon all in the room in which he is located. He is generally of low habits, as a rule, certainly very low habits; all his tastes and tendencies are of a bad and unsatisfactory character. He is also given to be very seditious as a rule (that is one of the great objections to him); to subvert discipline; to be disrespectful to the staff, notably to the superior officers; to defy them; and altogether I may say he is an element of discord."

Further on, speaking of the difference between a criminal and a non-criminal lunatic in relation to treatment, Dr. SHEPPARD gave evidence as follows:—

"I have no doubt myself that many of these criminals have proclivities to insanity; they come of a bad type of humanity altogether; they inherit a very strong tendency to commit crime, very many of them. You have only to look into their faces to see that, but taking the vice and the insanity together, and mixing them up, they become very nice compounds; and in many cases there is what I may term a maximum of crime and a minimum of insanity. They exercise a most prejudicial influence upon the other inmates, in whose case, as a rule, the insanity is the maximum and the crime is the minimum."

the Commission, evidently, did not realise the force of this meaning; indeed, there is nothing to lead any impartial reader of the Report to suppose that the main subject of the sentence was understood at all! The Commission is of opinion that when medical superintendents complain of "criminal lunatics" they mean *ex-criminal lunatics*—that is to say, persons who having been criminals have become sane, but have now in some way expiated their crimes, or at least written off the rolls of the criminal classes. Having arrived at the conclusion "that opinions (medical opinions) as to the offensiveness of criminal lunatics to ordinary pauper lunatics, rest chiefly on experiences relating to criminal lunatics, who are really ordinary pauper lunatics," and on experiences "of other lunatics in whose history none had presented itself," the Commission proposes to amend matters by so modifying the warrants issued by the Secretary of State that when a criminal is sent to an asylum he shall become an *ex-criminal*—in short, a person of the very class on the observation and experience of which the adverse opinions of medical superintendents are based! This *reductio ad absurdum* of the question at issue is worthy of the Commission and of the Report. In short, the whole inquiry has from first to last been farcical as regards the main issue in which the medical profession is interested. It may be expedient to report on the mental condition of "Queen's pleasure lunatics" at the end of each year, and that the Secretary of State should issue a fresh order of detention every third year. It may be well to give the wards set apart for lunatics at Woking prison the status of a criminal asylum; and it may conduce to the general convenience if Broadmoor asylum is reserved for specially bad cases. It is even possible that the pressure of the main "grievance" may be mitigated if an agreement be entered into by the Prison Commissioners with conveniently situated county and borough asylums to receive from local prisons those insane prisoners who would not be willingly received until after the expiration of their sentences by the asylums of their own counties; and, finally, that alleged insane prisoners from local prisons should be sent to a criminal lunatic asylum. These reforms, we say, may do some good; but what the Commission was asked and expected to recommend was a distinct and final severance of the two classes of lunatics. It is no answer to the protest almost unanimously urged against sending criminals or *ex-criminal lunatics* to ordinary asylums to say, as the Commissioners say, that a large proportion of the ordinary pauper inmates of asylums are of a low type, and may have been criminal. These are not sent to the asylum stained with crime, or with recent prison associations upon them! If there had only been on the Commission one or two men possessing any experience in the actual management of county and borough asylums, the result might have been different. As it is, we can only regret that the commission was ever issued. The Report will only tend to confirm a practice which is most pernicious in its effect on the ordinary insane, and which helps to keep up the most mischievous impression that asylums are prisons and workhouses rather than hospitals—an impression which it is, above all things, desirable to remove.

It is premature to announce, as if on authority, that the Government has determined to bring in a Medical Bill. The Report of the Commissioners is, we believe, still under

the grave consideration of the Privy Council, and the practicability of devising machinery for carrying out the recommendations of the Commissioners is being considered. Moreover, the earnest efforts of the Lord President and of Mr. MUNDELLA are on the side of those who wish to end the miserable chaos and competition of licensing authorities. It would be strange indeed if a Liberal Government could be indifferent to suggestions for improving medical education, and making the tests of it fairer for the medical student and more satisfactory for the public—suggestions emanating from a Royal Commission of the highest authority, of its own appointment, and which coincide in the main with similar proposals from previous Governments, and with a large mass of public and professional opinion. It would indeed be remarkable if the Government declined to put such suggestions into the form of practical and effective legislation. No doubt such legislation may involve the disappearance of a few small medical corporations. Yet what is this but that happy "timely death"—as Sir JAMES PAGET puts it—which should be provided for institutions for individuals. It is not conceivable that a Government which is ready to reform the Corporation of London will shrink from a reform that may be unacceptable to a few medical corporations, which, as Professor TURNER says, are "an anachronism." That the great Universities, or even the Royal Colleges of the profession, will suffer materially we do not believe. But even if they should, they are not entitled to demand exemption from legislation that will make medical education better, medical examinations fairer, and the Medical Council something more than a clique of medical corporations. Though, then, we repeat, it is premature to announce that the Government has determined to bring in a Bill, there are ample grounds for believing that it will do so; and that if the Bill be worthy of the Government and of the questions to be legislated on, it will have the effective support of a large proportion of medical men and the gratitude of future generations of medical students, who are too little considered in this matter.

## Annotations.

"Ne quid nimis."

### HEALTH OF THE ARMY IN EGYPT.

THE reports which reach this country of the state of health of the troops now remaining in Egypt appear to confirm the opinion we have repeatedly expressed that the high ratio of sickness and the mortality from typhoid fever were the results of the hardships the men had undergone in the brief but very trying campaign, and especially of the quality of the water they were unavoidably compelled to drink after the destruction of the canal, and that they would speedily disappear under improved sanitary conditions. It may be remembered that General Sir A. Clarke, R.E., was sent out to inquire into the nature and extent of the barrack accommodation available for the force which is to be left in temporary occupation. He has performed this duty, in conjunction with the Principal Medical Officer, and arrived in England on Wednesday. It is stated that he speaks confidently of the improved condition of the troops, chiefly as shown in the reduction of the number of sick, the milder type of disease, and the great decrease in the deaths. He is reported to have expressed his opinion that as soon as the

[Dec. 16, 1882.]

troops have been moved into the barracks and palaces which have been provided for their use and have undergone the very necessary process of cleaning, they will rapidly be restored to health and efficiency.

### MORTALITY IN SUNDERLAND.

RECENT mortality statistics for the borough of Sunderland present some remarkable features, indicating a sanitary condition which calls for energetic action on the part of the local public health authority. During the past eighteen weeks—that is, since the early part of August—the annual death-rate in the borough has averaged 32·9 per 1000, and in the week ending the 25th ult. it was equal to 47·8. That this excess in the rate of mortality was mainly due to exceptional zymotic fatality is evident from the fact that during the period under notice the death-rate from the principal diseases of this class averaged 9·8 per 1000, or more than three times the mean rate from these diseases in the same period in the other large English towns. Measles, scarlet fever, and “fever” have all recently shown epidemic fatality within the borough. Measles, from which but one death was recorded in the first six months of this year, caused 46 deaths in the three months ending September, and no fewer than 123 in the first ten weeks of the current quarter. Scarlet fever fatality has also recently assumed excessive proportions, resulting in 60 deaths since the beginning of August. The deaths referred to “fever,” which were 5, 14, and 27 respectively in the first three quarters of this year, rose to 28 in the first ten weeks of the current quarter. Such an aggregate of zymotic fatality affords conclusive evidence of an exceptionally unsatisfactory sanitary condition. The four months under notice embrace a great portion of the period of summer diarrhoea fatality, and it may be noticed that the annual death-rate from this cause during last summer quarter was 3·2 in Sunderland, against 2·4, the mean rate in the twenty-eight great towns. With regard to the mortality statistics of Sunderland since 1870, when the Registrar-General first published uniform statistics of disease mortality for some of the largest English towns, it should also be borne in mind that this town suffered more severely than any other from the remarkable small-pox epidemic of 1870-71; also that the average death-rate from scarlet fever and “fever,” as well as the rate of infant mortality, during the twelve years 1870-1881, showed a marked excess compared with the mean rates in the largest English towns. The death-rate from scarlet fever in Sunderland during the six years 1876-81 averaged 1·70 per 1000 (more than double the mean death-rate in the large towns),—a fact which, taken alone, should prompt a rigid investigation of the health-condition of the town.

### THE COMPOSITION OF CERTAIN ORGANIC LIQUIDS.

THE *Strongylocentrotus lividus* (Brandt), belonging to the class of echinoderms, contains in its interior a liquid which is taken by the inhabitants of certain districts in the South of France under the impression that it is a digestive tonic, and it seems to have such an action when taken in the dose of half a wineglass daily. It thus constitutes a sort of animal mineral water. Its composition has been ascertained by MM. Mourson and Schlagdenhauffen. When fresh it is neutral in reaction, but in a few days it becomes turbid, acquires a fetid odour, and deposits brownish flocculi. Its reaction is then alkaline, and it contains ammoniacal and sulphuretted compounds; 1000 parts of it contain 959 of water, and 41 of solid matters, of which 37 are fixed salts, consisting chiefly of chloride of sodium, with some chloride of magnesium, small quantities of the sulphates of calcium and magnesium, and traces of chloride of potassium, and carbonate of calcium. There are also three parts of organic

matters containing fatty matters and a little albuminoid matter.

liquid apparently consists of sea-water, with an excess of carbonic acid and nitrogen (as if of respiration), excrementitious matters, which are probably derived from the organs of the animal.

The ptomaine seemed to have an active effect was not fatal, because the obtained was insufficient to produce

It is conjectured that the ptomaine is present in some bivalve mollusca, certain time of the year causes poison. The same investigators also analysed the hydatid cysts and cysticerci. ### VENTILATION OF THE UNDERGROUND RAILWAY.

SOME years ago a great stir was made about the tunnels of the Underground Railway, and the reason, as the unfortunate deaths which then occurred to show.

Since that day the outer circle has completed, and impelled partly by a wholesome sense of need for ventilation, and partly by an equally natural

not wholly disinterested yearning for “more light” the Metropolitan District Railway Company is now

vouching to persuade the Board of Works that it ought to be allowed to discharge its foul accumulations of steam and smoke and impure air into the atmosphere of the

recreation gardens along the Thames Embankment. This plea is based on the assumption that the Metropolitan District Railway must needs discharge its aerial abominations somewhere. The obvious reply to this demand

on the lines of the memorable rejoinder to the plea “must live”—namely, “I fail to see the necessity.” A man

doubtless much to be desired by the Company and its patrons that there should be abundant ventilation, and that insignificant portion of the community which does not

either hold shares in the Railway Company or travel on its

ptomaine, a little urea, from this analysis the water, with an excess of carbonic acid and nitrogen (as if modified by the products of respiration), excrementitious matters, and some products which are probably derived from the organs of the animal.

doubtless much to be desired by the Company and its patrons that there should be abundant ventilation, and that insignificant portion of the community which does not

either hold shares in the Railway Company or travel on its

has a right to be considered. In plain truth the way Company has not any valid claim to be allowed to be a nuisance to the frequenters of the gardens on the bankment. We cordially endorse the argument of a temporary, that the Railway Company should be enjoined to consume its own smoke or to employ compressed air as a live force. It is enough to have the Embankment embowered with railway stations. The Board of Works is simply doing its duty to the great majority of the public in giving permission to the Company to break the ground and make the gardens useless by poisoning their atmosphere.

#### THE CONTAGIOUS DISEASES ACTS AT DEVONPORT.

AT the annual meeting of the subscribers to the Royal Albert Hospital at Devonport, which has been recently held, many statements were made in regard to the working and efficiency of the Contagious Diseases Acts, of sufficient weight and importance to give them more than a local interest. The report of the Select Committee of the House of Commons has materially strengthened the hands of the supporters of these Acts, and that this is recognised by their antagonists is immediately apparent. Tracts and addresses have been circulated in Plymouth, Devonport, and Stonehouse, urging that the report is one-sided and not in strict accord with the evidence laid before the Committee. It is therefore of the most importance that we should have laid before us the views of those inhabitants in the Three Towns who subscribe and support the local hospital in which the patients are detained who are under these Acts, as well as the views of the chief naval authorities in charge of the Government establishment at Devonport. These are most explicitly stated in the report of the Hospital Committee and the speeches of Mr. Edward St. Aubyn, its chairman, Mr. J. May, a former mayor of Devonport, Admiral Sir Houston Stewart, K.C.B., and the other admirals and civilians who were present at the annual meeting, and are fully reported in the *Western Morning News* of the 23rd ult. The opponents of the Acts now endeavour to show in a most characteristic and ingenious manner that they are unnecessary in that district. Before the Select Committee Inspector Anniss had given perhaps the strongest and most convincing proofs of their efficiency that had been laid before the committee. He showed the value of these Acts not only directly so far as the diminution of venereal disease is concerned, but also in their deterrent and reclamatory effects, which Mr. Stansfeld and his supporters so persistently urge as being beyond the scope of, and altogether apart from, their necessary operation. The Watch Committee of the Devonport Council, evidently jealous of the activity of the special inspector, claim that sufficient importance has not been given to the labours of their own superintendent. So that instead of allowing that at any rate much good had been done, the supporters of the opposition to the Contagious Diseases Acts are actually trying to make capital out of petty local rivalries, in which the only dispute is as to whom the credit of the present condition of the Three Towns is due. If the only object and effect of the Acts is to perpetuate, extend, and render safe the immorality of the districts under the Acts, why should they not at once confess that their estimate of their value in the Plymouth district is at direct variance with the local one? We should then have no difficulty in forming our own conclusions as to which is the more likely to be the correct estimate? During the past year the number of patients in the lock wards has greatly diminished, and at the end of last month there were only twenty-eight patients in the hospital. This is the smallest number since the introduction of the Acts, and can it be seriously urged that this does not show that they have been most effectual in dealing

with the disease, against whose spread they were especially introduced? Sir Houston Stewart's remarks on the efficiency of similar measures at Malta are very important, for it is continually stated and restated that such restrictions have always been found, in the foreign ports in which they are in operation, ineffectual against the spread of syphilis; and evidence on this point is rarely of such cogency and force as the statement we quote from the worthy admiral's speech:—

"The President, after having thanked the meeting for the compliment paid him, said: 'With regard to the Contagious Diseases Acts I should like to say a few more words. Some years ago I commanded a vessel in the Mediterranean which had a crew of 1350 men. It is the custom on that station for the fleet to winter for six months at Malta, and then be ready to go to sea. I am now speaking of my own vessel, not others of the squadron. During the six months we lay in Malta harbour the Acts were in force, and when the cruising season came round my ship was able to go to sea without any venereal cases. During the absence of the fleet from Malta some influence prevailed with the then Governor, and the Acts were suspended. Well, the ships returned to Malta and wintered there under the altered circumstances, and in my ship alone when the cruising season came round again we were obliged to leave thirty men behind suffering from disease. You know what that means—three or four guns unmanned, besides other things which had to be neglected. The then Commander-in-Chief in the Mediterranean, and who has since been Commander-in-Chief at Devonport—I mean Sir W. F. Martin—took the subject up. The Governor was a man of sense and judgment, the Acts were put in force again, and with what result? The following winter we again went to Malta, and were able to go to sea in my ship at the end of six months without any cases of disease.'"

#### HEALTH OF INDIAN CIVIL SERVANTS.

A PANIC has arisen with regard to the physical and mental deterioration which, it is alleged, has set in among the "competition wallahs" during the last few years. It is stated that out of one hundred and odd civilians appointed to the Bombay Presidency since the institution of the competition system, nine have died, two have been forced to retire on account of physical debility, ten more were considered quite unfit for their work on account of bodily weakness, two have been dismissed from inability to ride and uncouth manners, and eight have become positively insane. Although it is probable that this statement is somewhat exaggerated, still for some time it has been well known that a very considerable proportion of the civil servants in all three Presidencies appointed under the competition system have been invalided, and that they compare very unfavourably both in physical and mental stamina with those who were appointed in the days of the old East India Company. It is sought to refer the collapse to the over-strain caused by the "mad fad of cramming" induced by the competition system, and we think that a great portion of the evil may in truth be fairly laid at the door of this system. But it must not be forgotten that during the last twenty years the conditions of life in India have considerably changed. The introduction of railways and telegraphs has quickened the pulse of Oriental life in a wonderful degree, and the strain on the nervous energies has enormously increased; nor has the supply of civil servants at all kept pace with the rapid development of the country, so that the demands made on all members of the administration have increased proportionately. Such a strain, which might be borne with impunity in Europe, certainly cannot be long maintained in India without serious consequences being entailed; and when it is considered that the majority of the civil servants come to the task with their nervous systems already overtaxed, and all the "go" taken out of them by years of cramming, it is not to be wondered at that a breakdown occurs. Another factor at work is, undoubtedly, that though the "competition wallah" is supposed to be a

perfect prodigy of learning, yet his practical knowledge of the world is limited, so that when placed in situations which require tact, diplomacy, and common sense, he suddenly finds that his books can no longer help him. We know nothing so trying, or more likely to lead to mental breakdown, as to be placed in positions of responsibility without having the requisite gift. It is not long since we had the pleasure of reading some letters of William Augustus Brooke, who at the commencement of the century was judge of the Court of Appeal, and lived to become the father of the Indian Civil Service. These letters show that in those days it was possible for civil servants to perform their duties with vigour, energy, and efficiency, without the sacrifice of health. Few ever thought of leaving India till their fortunes were made and their period of service completed; those who were invalided home may have brought back "livers" impaired with curry and brandy pawnee, but not shattered nervous systems.

### VASCULAR DILATATION.

THE mechanism of dilatation of the vessels has for a long time occupied the attention of MM. Dastre and Morat. Previous researches have led them to conclude that the sympathetic is a mixed system of nerves, containing fibres which dilate as well as those which constrict the vessels. The investigators have shown that this is true of the vaso-motor fibres for the neck, face, ear, and limbs. This principal point having been established, it becomes easy to follow the course of the nervous excitations, which, proceeding from certain parts of the sensory apparatus, provoke reflex dilatation of the vessels in various parts of the organism—a course which includes, necessarily, centripetal fibres, a centre, and the efferent fibres contained in the sympathetic. As a type of the reflex, they have recently studied that which is known as the auricular reflex, or Snellen's reflex; and their results have been communicated to the Académie des Sciences. The principal sensory nerve of the ear is the great auricular, a branch of the cervical plexus. Sensory impressions on the external ear are by this nerve conducted to the spinal cord by the second or third cervical roots. If the nerve is divided and its central end stimulated, reflex congestion of the ear is produced, which is some times enormous in amount. This vascular dilatation is preceded by a slight constriction if the exciting current is of moderate intensity; but if the current is strong the dilatation occurs at once. The effect is produced by the mechanism of the vaso-dilator nerves which come from the spinal cord by the eighth cervical and first two dorsal pairs, and which pass thence into the sympathetic. In order to ascertain the whole of the course traversed by the excitation, it is only necessary to find its path in the spinal cord. For this purpose MM. Dastre and Morat have made the following experiments. In a white rabbit the spinal cord was divided unilaterally, somewhere between the third and seventh cervical pairs. The operation was followed by a bright congestion of the whole head, especially of the ear, on the corresponding side. The congestion disappeared at the end of a few hours; it must therefore be ascribed to an excitation, and not to a paralysis. When the circulation had become normal the two auriculo-cervical nerves were divided and then the central extremities were stimulated. On the normal side reflex congestion at once resulted; but on the side operated on no effect was produced. The operation was also performed in another manner. Instead of a hemisection, the cord was divided entirely, artificial respiration being maintained. After one or two hours, when the congestion from the operation had disappeared, the auriculo-cervical nerve on each side was stimulated, but no effect was produced. The conclusion is, that the interruption to the continuity of the cervical cord between the second and eighth cervical pairs abolishes the

vaso-dilator reflex of the ear. The integrity of this segment is therefore a necessary condition for the phenomenon. A division of the cord below the sixth dorsal has no effect on the reflex.

### THE COLD WEATHER AND PARISH RELIEF.

THE inclement weather of the past ten days has again thrown many labourers and others out of their employment, and a considerable amount of distress has been the consequence. Should the cold still continue to be the strain on the resources of the poor will become very great, and much will depend on the action of the various local guardians throughout the kingdom, whether this period of distress can be tidied over without adding materially to the pauper roll. Liberal out-door assistance will enable many to struggle on till more genial weather returns, but if not given with a niggard hand then many a respectable man will be driven to seek refuge in the workhouse, and become for ever pauperised. This caution we repeat is needed since the illiberal and in the end expensive policy of refusing adequate out-door relief has been already demonstrated. We notice that a death is reported from Leeds Green which, according to the verdict at the inquest, was accelerated by the unfeeling treatment and cruelty of a part of the parish officials." In this case it was shown that had adequate out-door relief been afforded the period of distress might have been tidied over. We would urge upon medical men who visit among the poor, district nurses and the clergy, the importance of seeing that the local authorities do their duty. We need hardly remind our readers how heavily the inclemency of the present winter has taxed the resources of the hospitals whose wards are now full to overflowing, but whilst urging the public to support them liberally, we would also impress upon the propriety of only giving their letters of recommendation to the absolutely necessitous.

### HYDROPHOBIA.

A CASE of death from hydrophobia has been reported from Rochdale. According to the report of the inquest contained in the *Leeds Mercury*, it appears that in June last a man went into a shoemaker's shop in Rochdale, and lay down; the owner of the shop went to stroke it, on which the man bit him in the hand. On Nov. 24th the man presented the symptoms of hydrophobia—some spasm on an attempt to drink. By the advice of a medical man, he took a cup of bath, and seemed to be better. Apparently growing worse he was taken, on Nov. 27th, to the workhouse, and there was "seized, and his arms strapped," treatment which a son declared was "barbarous." The chief attendant is a "imbecile ward," states that on admission the patient was very violent, and became insensible at times. Dr. Fox, the surgeon, ordered him to be put into a padded room. He was accordingly put to bed, and some medicine was administered, and two inmates were directed to attend to him. He died at eight o'clock the following morning. The coroner expressed the opinion that the patient's arms ought not to have been strapped. It is not easy to form a just opinion of the treatment of such a case without further details than the report affords, but it certainly does not seem to have been very satisfactory, although we are scarcely inclined to apportion the blame in the same way as the coroner. In the later stages of hydrophobia there is often considerable maniacal violence, rendering some mechanical restraint inevitable; and if a patient in such a state is taken to a workhouse in the absence of the medical officer, it is natural that the officials, recognising the necessity of restraint, should apply it in the way they are accustomed to adopt in violent cases of insanity. But why, we would ask, was the patient taken to the workhouse at all? What could be done

culated to aggravate his excitement than forced removal to such a place, during the stage of the disease in which the mental state is most disturbed? Surely a master shoemaker, living apparently in his own house, could have been treated here during the brief duration of such a disease. The only chance of recovery, infinitesimally small though it be, is afforded by the maintenance of absolute tranquillity of mind and body, and its furtherance by sedative treatment. If a case of hydrophobia is removed at all, it should be in the early stage of the disease, before excitement sets in. But removed, why was such a patient taken to the workhouse? Bichdale, according to the Medical Directory, contains an infirmary and dispensary, with nine beds, four surgeons, and resident medical officer. What is the use of such an institution if a case of hydrophobia has to be taken to the workhouse?

#### ILLNESS OF THE POSTMASTER-GENERAL.

WE regret to learn that Mr. Fawcett's condition during the week has been rather perilous. On Saturday, Dec. 9th, while the fever was favourably pursuing its course, he had repeated attacks of hæmorrhage proceeding from the upper part of the air-passages, and accompanied with spasmodic cough and a sensation of choking. There have been several slight returns of the hæmorrhage since, and they cause alarm not only from the amount of blood lost, but also from the danger of the blocking of the bronchial tubes with blood. The clots and fibrinous casts lodged in the smaller bronchial tubes, chiefly by the hæmorrhage of Saturday last, prevent the ingress of air, and create irritation which may account for the continued elevation of the pulse and temperature. As long as these clots and casts remain they are able to excite still greater mischief in the lungs; but we are glad to learn that the process of expulsion has been going on favourably during the last few days, and if this continues satisfactorily, and there is no recurrence of serious hæmorrhage, the medical attendants think they may entertain the hope that this valuable life may be spared. The anomalous character of the symptoms presented in Mr. Fawcett's case renders it difficult to give any satisfactory explanation of their origin. This, however, will probably be carefully investigated at a future time, and the sanitary conditions of his own house and of his rooms at the Post-office will receive due attention.

#### A NEW DEODORISER.

A STATEMENT was recently made at a meeting of the Burslem Town Council by Dr. Oldham that smoke is really a guardian angel, and instead of a nuisance is really a blessing in disguise. Dr. Oldham contended that the smoke from the factories of his district, blending with the atmosphere, acts as a deodoriser, and thus counteracts the evil effects of bad drainage. The theory that there is virtue in smoke possesses, perhaps, the proverbial two grains of truth hidden in the bushel of chaff. The deodorising properties of charcoal are well known. It has a wonderful affinity for, and destructive power over, noxious gases. A small handful enclosed in a respirator and placed across the nostrils makes imperceptible to the most delicate olfactory nerve the strongest of odours. The question is, To what extent does coal, smoke, or soot possess the deodorising and air-purifying properties of charcoal? The healthiness of London, compared with other large towns, is well known, and the fact that it is one of the smokiest inhabited spots on the earth's surface is admitted by all; and the question again arises, Is there any connexion between these two facts? If the smoke nuisance has to be tolerated to cure the effluvia of drains, we should, however, prefer attention being paid to the old motto that "prevention is better than cure."

#### FASTING IN ACUTE RHEUMATISM.

DR. CAREY E. WOOD, professor of chemistry in the medical department of Bishop's College, Montreal, in an article in the *Canada Medical Record*, recommends starvation as the treatment of acute rheumatism. He gives a history of seven cases restored to health by simply abstaining from food for from four to eight days. Amongst other advantages of the treatment cardiac complications are almost entirely averted. And he says he could give the history of forty more from his own practice. His patients were allowed to drink freely of lemonade or of cold water. In no case did the treatment fail! He is inclined to think from these cases that rheumatism is only a phase of indigestion, and that by giving complete and continued rest to all the viscera that take part in digestion the disease is attacked *in ipsa radice*. If we mistake not, Dr. Gill of Canterbury has anticipated the author as regards his theory of the origin of the disease in disorders of the viscera concerned in digestion. We are quite disposed to think that the rôle of starvation or fasting in therapeutics is far more considerable than has yet been described. It is an old Scripture that "fasting" is half the battle in expelling some devils. But we confess to being not a little sceptical in regard to Dr. Wood's remedy for rheumatic fever—a disease occurring often in subjects of delicate constitution. Besides the disease itself is most exhausting, being compounded of pain, sweating, and high temperature, and these extending over a long time. While it is our duty to record such statements as Dr. Wood's, it is equally our duty to say that they do not commend themselves to us as embodying the truth either as regards the pathology or the treatment of this remarkable disease, which, till Dr. MacLagan's discovery of the power of salicin over it, was an opprobrium to medical science, and which even now in some cases taxes all the resources of the physician.

#### THE PARIS FACULTY OF MEDICINE.

AT the last meeting of the Academical Council the Deans of the Faculties of Medicine, of Science, and of Literature, and the Directors of the Higher School of Pharmacy, and of the Preparatory School of Medicine read their annual reports. The Faculty of Medicine now comprises four separate departments: the ancient Faculty, the Practical School (which is temporarily lodged in the buildings of the former College Rollin), the Botanical Garden of the Rue Cuvier, and the Clinical Hospitals. The number of students who followed the course of lectures for the last year (Oct. 16th, 1882, to 1883) was 4209, this being exclusive of fifty foreigners and thirty-nine women, the latter being thirteen fewer than last year. The number of examinations at the Faculty of Medicine was 6076, nearly a third of whom were "plucked."

#### ISOLATION HOSPITAL AT TAUNTON.

WE learn from a report issued by Dr. Henry J. Alford, that considerable success has attended the establishment of the Taunton Sanitary Hospital. As the value of the institution has become known, its use for the purposes of isolation has steadily increased, and the total admissions during the past twelve months have amounted to seventy-six. And not only so, but the social status of the patients is also improving. When the hospital was first opened, hardly any but paupers were received, but now the cases isolated come to a very important extent from those classes amongst whom infectious diseases become so grave a source of danger to the public. Thus, cases were admitted from the houses of tradesmen whose wares might otherwise have become vehicles of infection; from dairymen's premises; from the homes of postmen, labourers, and artisans, persons who, if they had continued their employment at the same time as

[DEC. 16, 1882]

infection prevailed in their families, could hardly have failed to have spread disease. It also appears that in no single instance during the year had there been any need of compulsion in order to secure isolation. Dr. Alford's report fully bears out the conclusions arrived at by Dr. Thorne Thorne, who, in his Report on the Influence of Hospitals for Infectious Diseases, shows that in nearly every case where a suitable hospital has been provided by a sanitary authority, the usefulness of the building for the purposes of the very classes for whom it was most wanted has steadily increased, and this, with only the rarest exceptions, without any need for resort to the compulsory powers of the Public Health Act, 1875.

#### THE FULL QUALIFICATION FOR POOR-LAW APPOINTMENTS.

THE guardians of Walton-on-Thames would appear to consider the requirements of "full qualification" in applicants for medical officerships as a piece of "red tape." On this view they have given an appointment to Dr. Macdonald, a graduate of the University of Edinburgh, but without a surgical qualification, though two other gentlemen were in the field with the double qualification. The Local Government Board have sanctioned the appointment of Dr. Macdonald up to Christmas, but Dr. Macdonald does not undertake to get a surgical qualification till June; and on the "red tape" view the guardians have appointed him, in excess of the sanction of the Local Government Board. We certainly think that while the present absurd system of partial qualifications exists it should be applied impartially by guardians of the poor. It is hard for those who, in obedience to the system and the law based on it, have taken two qualifications to see the law voted "red tape." We are equally sorry for Dr. Macdonald, who, too, is a sufferer by the state of the law. The sooner the law of qualification is simplified and made equal the better for all.

#### PASTEUR'S RESEARCHES.

A LETTER was read at a recent meeting of the Académie des Sciences from M. Pasteur, giving an account of his progress in some researches in which he is at present engaged in the district of Vacluse. He has gone there to investigate a disease of pigs, which, in one valley of the Rhone, has recently been fatal to 20,000. The disease is called "le rouge des porcs;" and M. Pasteur announces that he has discovered its cause to be a very minute organism, which in point of size resembles that of chicken cholera. It differs, however, in its physiological properties, since it has no action on fowls, but it is fatal to rabbits and pigs, especially to white pigs. M. Pasteur has convinced himself, by experiments, that one attack affords protection against another, and he has succeeded in inoculating pigs with organisms which have been weakened by culture, and in thus rendering these animals insusceptible.

#### HOMŒOPATHY AT THE ANTIPODES.

THE Tasmanian papers contain interesting accounts of the fate of a petition to the Board of the Hospital of Hobart Town, said to be signed by 1700 people, to set apart a ward for the treatment of cases under the homœopathic system. It should be stated that the Board consists of thirteen laymen and four medical officers. Mr. Dodwell asked the chairman for a return of the number of persons admitted into the hospital who had wished to be treated homœopathically. The chairman said that no such application had ever been made. In the discussion of this question Lord Beaconsfield's case naturally turned up, with disastrous results to the homœopathic argument. The usual statistics showing almost the entire abolition of mortality from fatal

diseases under homœopathy were trotted out, but without effect. The medical officers of the Brompton Hospital, and the Board unanimously negative the proposal. Even the gentleman who voted heartily with the majority. When he saw the necessity to abolish their shabby statistics they deceive no one, and homœopathy with an old system of practice. Nobody with a grain of sense would be persuaded by such statistics to forego the use of good doses of well-recorded cases of pneumonia without a death, exceeds all the statistics even if the question were one of statistics.

#### CHRISTMAS FESTIVITIES.

FEW people of middle age view with indifference the present season brings with it makes them unjust to those who at the same time are able to enjoy the good things if only in moderation. Middle-aged prejudices are against plum-pudding; yet this article of food, yielding a force equivalent to 250 horse-power, is an admirable vehicle for the administration of diet as a rule usually objected to by children in reasonable quantity, is certainly to be called "wholesome" cakes, which have a good composition. A good wedge of cold plum-pudding is an unwholesome lunch for young and growing people, too, are often able to compete with members of the family in the enjoyment in a manner that amazes and discourages relations. The fact is, as has been happily preserved, so that a man who in the prime of life is a martyr to dyspepsia, by reason of the gastric nerves, in his later years, when blunted, and when therefore his peptic powers pursue their chemical work undisturbed by eating and drinking with the courage and success

#### HOSPITAL SUNDAY FUND.

ON Wednesday the annual meeting of the Hospital Sunday Fund, being the clerical representatives of the various contributing congregations, held in the Egyptian Hall of the Mansion House, in the presidency of the Lord Mayor. The annual report of the past year disclosed a steady increase in the number of congregations contributing, and the total amount by £2289 the largest collection previously made. The amount collected was £27,700, from 1072 congregations. Last year it was £34,146, from 1338 congregations. The amount had been divided among ninety-three hospitals, fifty-two dispensaries, and £1380, or 4 per cent of the total, had been expended in buying surgical appliances for the sick poor. The working expenses amounted to £1132.

#### THE NEW MATRON AT GUY'S HOSPITAL.

THE success of the new matron at Guy's Hospital will depend entirely on the temper and purpose with which she enters upon her duties. If she be willing and intends to subordinate the nursing to the medical services of the institution—in short, to carry out the instructions of the medical staff—everything will go smoothly, and the hospital will regain its old prestige. We should have greater hopes of this result but for the appearance in certain lay papers of

raphs repeating the ridiculous fallacy of asking the al staff to co-operate with the matron. It would be s reasonable, and no more so, to ask a housewife to rate with her servants. Nursing is simply sick- ing, and the sick must be tended as the doctors direct. spital is solely intended for the purpose of "cure," i is a medical function. Nursing is an integral part of ork of cure, and it must, therefore, obviously be per- ed under medical direction. Unless this be once for all inally understood at Guy's Hospital, there can be no of peace or prosperity for this medical charity.

#### MARKABLE PISTOL SHOT WOUND OF THE BRAIN.

R Birkenhead correspondent writes:—Early last rday morning a sad event took place at Exmouth- t. A fishmonger and registered milk-seller named oh Teece got up at five o'clock, telling his wife eard burglars. He then went to the apartment of domestic servant, Jane Wainwright, aged nineteen, was in bed, and shot her through the head with volver, after which he shot himself and then swallowed contents of a bottle containing an aconite liniment. e afterwards gave himself in charge, and the police ved him and the servant to the Borough Hospital. e is not so much hurt; the bullet having been de- ed by the frontal bone, was found flattened between scalp and the bone at the top of the head, the most distressing symptoms of the dose of ite have now subsided. Wainwright is still in an edingly critical condition, a bullet having penetrated skull. The wound of entrance is just above the left row, through which brain substance has protruded. pistol must have been held very close as the girl's hair orched. Though there is no exit wound, and the bullet t therefore be lodged in the brain, the patient has done from the first. On visiting her on Monday evening, und she was able to tell her name and answer mple question. Her temperature did not exceed 102°, her pulse was regular, and but 64. Since then her dition is somewhat improved.

#### MR. GLADSTONE'S JUBILEE.

THOUGH, as medical journalists, we live in regions remote m the atmosphere of political strife, we are not the less irected in the character and history of our public men. e qualities and the capacity of a man like Mr. Gladstone constitute not only a national possession, but a physiological enomenon. It is in the highest degree gratifying to see r. Gladstone with no appreciable abatement of his energy d his power of serving the State. Whenever his own nsciousness may apprise him of such abatement, we have wish him a long and quiet evening of life, sweetened by e gratitude of his countrymen, the society of his friends, and the enjoyment of his own rich and endless resources.

#### THE METROPOLITAN FIRE BRIGADE.

THE Metropolitan Fire Brigade is overworked—that is to y, it is under-manned and insufficiently provided. The medy—the only remedy—for this evil is to make it a eparate organisation on the same footing as the Metro- olitan Police. Since the brigade has been under the etropolitan Board of Works it has simply been crippled in s action. The Board taxes the fire fund heavily for anaging the brigade, and the advantages of a responsible ersonal management, such as would be carried out by aptain Shaw, are sacrificed. Let the Brigade stand alone.

#### NETLEY HOSPITAL.

OUR contemporary, the *Builder*, under the head of "A Want at Netley Hospital," makes some very pertinent remarks on the unsuitable construction of the staircases for the carriage of patients up to the wards, and on the want of a lift for that purpose and for the service of the house. He asks "How is it that a building of this magnitude, dating, if we remember rightly, only so far back as 1857, should be unprovided with mechanical lifts?" Our contemporary does not appear to be aware that lifts do exist in each wing of the building, but his ignorance on this point is very excusable, as we believe they are never used. Whether they are so constructed as to be available for the transport of invalids, we are unable to say; but if not it may be fairly assumed that they could easily be made so. Certainly an inquiry should be instituted by the authorities at head-quarters as to the cause of their use being discontinued, and should this depend on their antiquated or defective construction, steps should be at once taken to have them made efficient. We understand there are large water-tanks on the roof of the building, which would render the application of the hydraulic principle to working the lifts a matter of very moderate expense.

#### GLASGOW ROYAL INFIRMARY.

THE new buildings and elaborate accessories provided by the Glasgow Royal Infirmary School of Medicine do not seem to have lessened the prosperity of its rival, the dingy old Andersonian School; which, indeed, has astonished friends and enemies alike by showing more signs than ever of vitality. It is understood that the managers of the Royal Infirmary have come to some conclusions regarding the rules they wish enforced to regulate the administration of chloroform in the Infirmary. What these rules are I cannot yet say, but the wisdom of framing any such code is very doubtful. Hitherto the surgeon administering the chloroform has borne the full responsibility of his action in this, as in any other professional matter. It is to be hoped that the managers, in removing chloroform from the ordinary list of drugs and hedging about its use with various conditions and rules, are prepared to share this responsibility with the surgeon.

#### MYOSITIS OSSIFICANS.

AT a recent meeting of the Vienna Medical Society Professor Podrazki exhibited a soldier affected with the rare condition which has been termed myositis ossificans. Four weeks previously the man had applied for treatment, on account of an intense inflammation of the muscles on the front of the right upper arm, apparently set up by severe gymnastic exercise. The muscles were large, hard, and uneven, and the elbow-joint was fixed in flexion. The hardness was removed, and some increased mobility was obtained, by massage and the application of cold. At the end of two weeks a hard, round, movable tumour developed in the flexor of the elbow, which was evidently due to an ossification of the brachialis anticus. At first it was movable, the upper part appeared to be cartilaginous, and it was evidently not connected with the periosteum. Podrazki has seen, in the course of nineteen years, two cases in the practice of Pitha quite similar to this in their characters. In those two cases neither iodide of potassium, nor any other treatment adopted, had any influence. In a discussion which followed, Professor Weinlechner stated that he had twice seen similar small spots of ossification in the muscles on the front of the leg, due, in each case, to a traumatic cause. Kundrat expressed the opinion that some supposed exostoses on the thigh proceed from muscles. Their form and seat correspond to certain muscles. Their greater frequency in

men, and especially in muscular individuals, suggest that their origin is traumatic. They constantly become adherent to bone in the course of their growth, and hence are commonly thought to be primary exostoses.

### THE ROYAL BARRACKS, DUBLIN.

VARIOUS paragraphs have recently appeared in the daily press in reference to the alleged insanitary condition of these barracks, and it has been stated that they are most unhealthy, and that numerous deaths have taken place from typhoid fever owing to the bad sewerage. We have made inquiries into the matter, and are in a position to state that during the past seven months there have been either five or six cases of enteric fever, which in a strength of 1134 men can hardly be regarded as an epidemic. Of these three died, one being Mr. Richmond of the Hussars. The drainage undoubtedly has been bad, but it is believed that it is now in an efficient condition, as an extensive system of main drainage has been carried out, more particularly at the cavalry portion of the barracks, while the floors of the infantry portion have been thoroughly cemented.

### SCARCITY OF SUBJECTS IN AMERICA.

A REPORT which has reached us from America shows that the scarcity of subjects in our metropolitan and provincial dissecting-rooms, to which we alluded at the beginning of the winter session, has prevailed there too. Philadelphia is just now excited over the capture of a band of grave-robbers, or, as they are better known in this country, resurrectionists, who were caught with six bodies, intended for the medical college in that town, in their possession. An investigation shows that the robbers had almost cleared one of the cemeteries. The recovered corpses have been identified, and the men are now in gaol waiting their trial. The dearth of material for dissecting is a subject that will shortly have to be dealt with, and some alteration be made respecting the present limited supply.

### THE HOSPITAL SATURDAY FUND.

THE Board of Delegates report that the sum collected this year amounts to £8872, being £500 in excess of the sum raised last year. Of this sum £6318 were the proceeds of collecting-cards in workshops, and £2160 from the street collection, superintended by 900 ladies. We cannot too highly praise the kindness of these ladies; but the result as a whole disappoints us, and is disproportioned alike to the means of the workmen of London, and the sacrifices of the fair co-operators. The fund is not yet worked in a satisfactory way. The collection needs to be taken differently.

### THE ETIOLOGY OF DIPHTHERIA.

FOR some time past diphtheria has been prevalent in and about Pilbriht, in the Guildford rural sanitary district; and certain peculiarities as to its development have received much attention from Dr. J. Smith, the medical officer of health. Mr. W. H. Power, medical inspector of the Local Government Board, is now engaged with Dr. Smith in learning all the circumstances under which the disease has arisen and spread; and having regard both to the exhaustive character which the inquiry is taking, and to the nature of Mr. Power's previous investigations into some of the more obscure questions affecting public health, the official report on the subject will be looked for with more than usual interest.

DR. PYLE has been re-elected representative of the Durham University in the General Medical Council.

A CASE tried the other day at the Toulouse assizes possessed no little pathological interest, as one of the three prisoners, a young man of eight-and-twenty, who was accused of committing a series of thefts from shops, had become insane from having, between the time of his arrest and his trial, simulated madness. When first arrested he made several attempts to escape, but finding that there was no chance of this he fell into a state of lethargy and pretended not to understand what was said to him. Three doctors were commissioned to examine him, but they reported him to be perfectly sane, and he was accordingly put into the dock with his two accomplices. He refused, however, to answer the questions which were put to him, and his counsel stated that though he had at first only pretended to be mad he had finally become so in reality. The Court, without directing the jury to acquit him on the ground of insanity, were so far convinced that such was the case that they adjourned the trial and ordered him to be removed to an asylum, pending a fresh examination of him by a specialist from Montpellier.

SURGEON-GENERAL JOHN GIBBONS, C.B., on the retired list of the Army Medical Department, died a few days ago in Dublin in his fifty-eighth year. The deceased was present at the battles of Alma and Inkerman, and at the siege of Sebastopol, for his exertions during which he was specially mentioned in despatches by Lord Raglan. He received the Crimean medal with three clasps, besides the Turkish medal, and was appointed a Knight of the Legion of Honour. He also served during the Indian Mutiny, and was decorated with the Indian medal. He was promoted to the rank of Surgeon-Major in March, 1870, and to that of Deputy Surgeon-General in 1876. In July, 1879, Mr. Gibbons was gazetted a C.B., and last June he was placed on the retired list of the Army Medical Department with the honorary rank of Surgeon-General.

THERE is now in course of erection at Birmingham a magnificent building called The Birmingham and Midland Eye Hospital. The old structure has been found utterly inadequate to the requirements of the 13,450 patients who annually cross its threshold. The committee, of which the Rev. B. Jones Bateman is chairman, have boldly grappled with the difficulty, and a new hospital worthy of its object and replete with the latest and best appliances, both surgical and sanitary, is gradually being reared. It is intended that the building shall be a model of what such an institution ought to be. The estimated cost complete is £20,000. Many munificent donations have already come in, one notably of £5000 from Mrs. Barra.

THE total number of vaccinations performed in Bengal in 1881-82 (says the *Indian Medical Gazette*) was 1,349,607. The percentage of success was 98.39. The compulsory Vaccination Act was introduced during the year into the towns of Rungpore, Rampore-Beaulah, Soory, Hooghly, Chinsurah, Pubna, Bagrah, and Howrah, and its working was unattended with difficulty. In the North-Western Provinces and Oudh the number of vaccinations was 767,235, with a percentage of success of 91.70 in primary operations.

MR. LUTHER HOLDEN, hon. secretary of the Stone Testamental Fund, asks us to state that the Executive Committee of the Fund propose to close shortly the list of subscriptions, and to remind the members of the Committee who have not paid their subscriptions that the money should be forwarded to James Shuter, Esq., M.A., 58, New Broad-street, E.C.

THE completion of the laboratory of the Johns Hopkins University, at Baltimore, has given occasion for the raising of the question whether it were better that the institution should become one of the already too numerous manufactories of practising medical men, or one devoted to the higher teaching of medical science. The *Medical News* (Philadelphia) strongly advocates the latter view, and suggests that the Johns Hopkins institution can, with great benefit, perform precisely the same functions in the United States as the Society for the Advancement of Physical Research does in England.

THE matriculations in the University of Glasgow for the present year number 2270, distributed among the various faculties as follows:—In arts, 1304; in theology, 98; in medicine, 623; in law, 196; in arts and medicine, 20; in arts and law, 16; in arts and divinity, 10; in medicine and divinity, 3. The total number of matriculations last session was 2321. It will thus be seen that the numbers attending the medical classes are well maintained, though at the beginning of the session it was feared that they would show a falling off.

DR. FERRIER is preparing for the press a new and enlarged edition of his work on "The Functions of the Brain," which will embody many new observations and experiments by the author, as well as a critical examination of the various experimental and pathological investigations of recent years bearing on the question of the localisation of cerebral functions.

DR. RUSSELL, F.R.S., Lecturer on Chemistry at St. Bartholomew's Hospital, is engaged, we understand, in making some experiments on London fog at the request of the Meteorological Council, his special object being to ascertain its chemical constitution. We trust that the investigation will be followed by practical benefit to the inhabitants of the metropolis.

THE death is announced of Dr. Dickson, President of the College of Physicians and Surgeons of Kingston, Ontario. Dr. Dickson began his professional studies at Belfast and Glasgow. He was the first President of the Medical Council of Ontario.

THE next Poor-law Conference for Yorkshire will be held in Halifax on the 21st December. The Right Hon. James Stansfeld, M.P., will preside, and his address is to be on "Recent [i. e., last session's] Poor-law Legislation."

PROFESSOR CURNOW, M.D., has been appointed Dean of the Medical Department of King's College, in succession to Professor Bentley, who has retired after nearly twenty years' service.

DR. FLAMINIO TASSI of Siena has published a report of four cases of erysipelas, which rapidly yielded to a saturated aqueous solution of picric acid, applied morning and evening with a camel-hair brush.

MR. H. F. MORLEY has been authorised by the Council of University College, London, to give a course of advanced lectures on Organic Chemistry.

WE have received from Mr. Fradelle of Regent-street an excellent photograph of the late Sir Thomas Watson, Bart.

AN outbreak of measles of a very serious character has within the past few days taken place in Newry.

## Public Health and Poor Law.

### LOCAL GOVERNMENT DEPARTMENT.

#### REPORTS OF INSPECTORS TO THE MEDICAL DEPARTMENT OF THE LOCAL GOVERNMENT BOARD.

*Enteric Fever at Galgate.*—The village of Galgate lies within the rural sanitary district of Lancaster and about four miles to the south of Lancaster town; it is enclosed on three sides by hills; it lies on a soil consisting of sand and gravel; and contains a population of 743 persons, who occupy 166 houses. Owing to the prevalence of enteric fever there the place has recently been inspected by Dr. Barry, one of the medical inspectors of the Local Government Board. As a rule the inhabitants are well housed, and the main sewers are efficiently constructed, and are maintained in good working order; but in other circumstances affecting health matters are far less satisfactory. Some of the wells have been voluntarily abandoned on account of their obviously polluted state, and as regards the seventeen that remain there can be little doubt but that many are equally subjected to pollution; indeed, Dr. Barry's description of the filthy surroundings of some of them, taken in conjunction with the porous nature of the soil in which they are sunk, amply suffices to show the risk of fouling which they must constantly undergo. Midden-privies prevail in the place, and some of the conditions of excrement disposal, both as to insufficiency of privy accommodation and as to filthiness of accumulations about houses, indicate neglect of a grave character. In 1881, apparently, enteric fever was introduced into Galgate and occasional cases occurred up to the end of July in this year, when the disease became more intense, some nineteen persons being attacked during the six succeeding weeks. The outbreak was, however, of a circumscribed character, and it was at once apparent that it was in no way due to any special milk-supply. Seven households were affected and they procured their milk from three independent sources, which afforded a supply to the village generally. But with one exception all the persons attacked lived in houses having one water-supply—namely, that derived from "Mackinson's well." The exceptional instance became also of crucial importance in deciding as to the cause, for the patient, though living far away from the suspected well, had been in attendance on a prior case of the disease at a house supplied by it, and she had there partaken of it. The intensity of the incidence of the disease, as in all outbreaks of enteric fever due to water, was mainly upon those between the ages of five and twenty-five years; thus from five to fifteen years the rate of attack was 66.6 per cent. of the total, and from fifteen to twenty-five years it was 41.1 per cent., the infants and the aged almost or altogether escaping. As regards the well itself, the description of its surroundings shows conclusively the facilities that existed for its pollution both excrementally and by other filth, and if further proof were wanted to identify its use with the prevalence of the fever it will be found in its chemical ingredients and in the fact that on its disuse by the inhabitants the outbreak immediately ceased. Unfortunately the story of the epidemic is associated with one of those misunderstandings between officers of health and their fellow practitioners, which, though happily not of frequent occurrence, tend seriously to bring disrepute upon the profession. In this case the medical officer of health, failing, as Dr. Barry says, "to secure the co-operation of" another practitioner, "was refused admission into the houses in which the disease was reported to exist, and hence he was unable to take any special action in the matter." On the other hand, the same officer appears not to have attached sufficient value to the indications of water-pollution which existed, and thus it came to pass that there was an all but complete absence of "that hearty co-operation so necessary in these cases." Dr. Barry concludes by strongly urging the necessity of a proper water-supply and an improvement in the means of excrement and refuse disposal for the village.

#### FEVER AT THE SEVERN TUNNEL WORKS.

At the meeting of the Bristol Urban Sanitary Authority on the 7th inst., Mr. Davies, the medical officer of health, reported the existence of typhus and enteric fever to a serious

extent amongst the workmen employed at the Severn Tunnel works. He knew, he said, of at least twenty cases in Bristol and the Barton Regis districts which could be directly traced to the works. These did not include any cases under the care of private practitioners or of club doctors. Three deaths had already occurred from the above-named fevers. Mr. Davies thought that Dr. Bond, who appears to have already reported on the outbreak, had somewhat under-estimated its severity.

#### THE DRAINAGE OF THE LOWER THAMES VALLEY.

The Lower Thames Valley Main Drainage Board have applied to the Local Government Board for a provisional order to extend the time allowed for carrying out the powers for which they were formed, and to suspend the penalties for permitting the flow of sewage into the river Thames. At the ordinary monthly meeting held on the 7th inst., a communication was received from the Local Government Board, intimating that an inquiry would be held with regard to such application. A hope was expressed that the forthcoming inquiry would not occupy another forty-five days, and cost the constituent authorities another £45,000.

#### VITAL STATISTICS.

##### HEALTH OF ENGLISH TOWNS.

In twenty-eight of the largest English towns 5453 births and 3794 deaths were registered during the week ending the 9th inst. The annual death-rate in these towns, which had been equal to 24.2 and 22.3 per 1000 in the two preceding weeks, rose again last week to 23.4. During the first ten weeks of the current quarter the death-rate in these towns averaged 21.9 per 1000, against 21.8 and 21.2 in the corresponding periods of 1880 and 1881. The lowest death-rates in these towns last week were 16.2 in Derby, 16.5 in Leicester, and 17.5 in Plymouth. The rates in the other towns ranged upwards to 29.4 in Blackburn, 31.0 in Leeds, 31.2 in Hull, and 35.5 in Sunderland. The deaths referred to the principal zymotic diseases in the twenty-eight towns were 472, showing an increase of 45 upon the low number in the previous week; 119 resulted from measles, 110 from scarlet fever, 81 from "fever" (principally enteric), 81 from whooping-cough, 39 from diarrhoea, 29 from diphtheria, and 13 from small-pox. The lowest death-rates from these zymotic diseases occurred in Brighton and Plymouth, and the highest in Newcastle-upon-Tyne, Liverpool, and Sunderland. Measles caused the highest death-rates in Hull, Cardiff, and Sunderland; scarlet fever in Blackburn and Newcastle-upon-Tyne; whooping-cough in Portsmouth and Leeds, and "fever" in Sunderland and Liverpool. The 29 deaths from diphtheria in the twenty-eight towns included 20 in London and 3 in Sunderland. Small-pox caused 5 deaths in London, 6 in Newcastle-upon-Tyne, and 1 both in Wolverhampton and Nottingham. The number of small-pox patients in the metropolitan asylum hospitals, which had been 68 and 70 on the two preceding Saturdays, declined to 62 at the end of last week; and only 5 new cases of small-pox were admitted to these hospitals during the week, against 7 and 15 in the two previous weeks. The deaths referred to diseases of the respiratory organs in London, which had steadily increased from 330 to 424 in the four preceding weeks, further rose to 447 last week; this number was, however, 41 below the corrected weekly average. The causes of 87, or 2.3 per cent., of the deaths in the twenty-eight towns last week were not certified either by a registered medical practitioner or by a coroner. All the causes of death were duly certified in Brighton, Portsmouth, Plymouth, Birmingham, and Cardiff. The proportions of uncertified deaths were largest in Birkenhead, Salford, and Halifax.

##### HEALTH OF SCOTCH TOWNS.

The annual death-rate in the eight Scotch towns, which had been equal to 24.3 and 24.8 per 1000 in the two preceding weeks, rose to 28.0 in the week ending 9th inst., and exceeded by no less than 4.6 the mean rate last week in the twenty-eight English towns. The deaths referred to the principal zymotic diseases in these Scotch towns, which had been 78 and 88 in the two previous weeks, rose to 128 last week, and were equal to an annual rate of 5.5 per 1000, or 2.6 above the rate from the same diseases in the English

towns. The fatal cases of whooping-cough, which had been 26, 19, and 21 in the three preceding weeks, rose to 39 last week, of which 21 occurred in Glasgow, and 11 in Dundee. The 24 deaths from diphtheria also showed an increase upon recent weekly numbers, and included 13 in Glasgow, and 3 each in Edinburgh, Greenock, and Paisley. "Fever" was also more fatal than it had been for some time, and caused 19 deaths, of which 7 were returned in Edinburgh, and 5 both in Glasgow and Aberdeen. The fatal cases of scarlet fever which had been 18 and 12 in the two previous weeks, rose again to 18 last week, of which 12 occurred in Glasgow, and 3 in Aberdeen. Twelve of the 16 deaths from measles were returned in Glasgow. The deaths referred to acute diseases of the lungs in the eight towns, which had been 167 and 139 in the two preceding weeks, further rose to 185 last week, and exceeded by 73 the number from these diseases in the corresponding week of last year. The causes of 100, or more than 15 per cent., of the deaths registered in the eight towns last week were not certified.

##### HEALTH OF DUBLIN.

The annual rate of mortality in Dublin, which had been equal to 29.2 and 25.6 per 1000 in the two preceding weeks, further declined to 24.9 in the week ending the 9th inst. During the first ten weeks of the current quarter, however, the death-rate in the city averaged 24.3 per 1000, against 20.7 in London and 19.6 in Edinburgh. The 168 deaths in Dublin last week showed a further decline of 5 from the numbers in the two previous weeks, and included 12 which were referred to the principal zymotic diseases, against 14 in each of the two previous weeks. These 12 deaths included 9 which were referred to "fever" (typhus, enteric, and simple), 2 to whooping-cough, one to measles, and not one either to small-pox, scarlet fever, diphtheria, or diarrhoea. The death-rate from these zymotic diseases was equal to 1.8 per 1000 in the city, while the rate from the same diseases last week was 2.9 in London and 3.6 in Edinburgh. The fatal cases of "fever" in Dublin, which had been 6 in each of the two previous weeks, rose to 9 last week, and exceeded the number in any previous week of this year. The fatality of "fever" in Dublin last week was nearly three times as great as the average rate in the twenty-eight English towns. The deaths from whooping-cough showed a decline from recent weekly numbers. Compared with the numbers in the previous week, the deaths of infants were more numerous, while those of elderly persons had declined.

##### THE LARGE EUROPEAN TOWNS.

Messrs. Behm and Wagner have recently issued a return showing population statistics for some of the principal cities of Europe, from which it appears that there are only ninety-two European cities having a population exceeding 100,000. Accepting this return to be correct, the large proportion of such towns situated within the United Kingdom is worthy of note. England alone contains nineteen towns with more than 100,000 inhabitants, in addition to which Scotland contains four and Ireland two towns with populations exceeding this amount. Thus, within the comparatively small area of the United Kingdom are situated twenty-five, or more than a quarter of the ninety-two, European cities reported by Messrs. Behm and Wagner. This proportion is very largely in excess of that which the total proportion of the United Kingdom bears to the entire population of Europe, showing a marked excess of urban aggregation in the United Kingdom, which renders its comparatively low death-rate still more remarkable.

##### THE SERVICES.

Surgeon-Major A. F. Churchill, who has been for some time in medical charge of the hospital for women and children at the South Camp, Aldershot, has been placed under orders to embark for Egypt.

Surgeon-General J. A. Hanbury, K.C.B., who was Principal Medical Officer of the Egyptian Expedition, is to remain for the present at Cairo, Sir Archibald Alison considering his presence desirable in consequence of the sickness which prevails among the troops.

The Lords Commissioners of the Admiralty have awarded

to Dr. Henry J. Domville, R.N., C.B., Honorary Surgeon to the Queen, the Good Service Pension of £100 a year for Inspector-Generals of Hospitals and Fleets, vacant by the death, on October 17th, of Dr. James W. Johnston, R.N., Honorary Surgeon to the Queen.

**ARTILLERY VOLUNTEERS.**—1st Forfarshire (not "Fife-shire," as erroneously given last week): William Chalmers Cowan, Gent., to be Acting Surgeon.

**RIFLE VOLUNTEERS.**—2nd East Riding of Yorkshire: Acting Surgeon Henry Morris to be Surgeon.

**ADMIRALTY.**—Staff Surgeon James Bradley to be Fleet Surgeon in Her Majesty's Fleet, with seniority of Dec. 5th, 1882; Staff Surgeon Charles G. Wodsworth, to the *Scrapis*; Staff Surgeon Alexander B. Trousdell, M.D., to the *Tamar*, vice Lambert; Surgeon Alexander W. W. Reid, M.B., to the *Tamar*, vice Richardson; Surgeon Alexander P. G. Gipps, to the *Defence*, vice Reid.

## Correspondence.

"Audi alteram partem."

### THE SCOTCH UNIVERSITIES AND MEDICAL LEGISLATION.

To the Editor of THE LANCET.

SIR,—Allow me to say that I decidedly object to the detached sentence which you quote in your leader to-day on "Scotch Universities and Medical Legislation," from my evidence before the Select Committee of the House of Commons on March 8th, 1880, being given as a fair or sufficient representation of that evidence, or of my views on the position and duties of the Scotch universities. The sentence you quote was a suggested amendment on a particular clause of a Bill then before Parliament. You will find the general view of our Faculty clearly expressed in the second paragraph of the paper from which you quote (Appendix No. 1, page 29). That was only one of the conditions, and my answer regarding it (No. 35) was: "That is so as regards that point." But you may find my views stated concisely in the evidence given last year before the Medical Acts Commission, in Scheme No. I., with reasons, the plan which we think ought to be adopted; and in Scheme No. II. one which, "if it be considered desirable to combine universities and corporations in a general joint scheme," "he thinks would interfere less than any other with the university system of Scotland, if applied in the manner he will explain." Along with the six heads of that scheme please note the four conditions attached (p. 307, and farther in No. 5846), and, preceding that scheme, the "considerations concerning joint schemes in which it is proposed to combine universities and corporations."

Since the evidence given from the Scotch universities before the Select Committee of the House of Commons in 1880, and before the Medical Acts Commission in 1881 was published, not a stone has been cast at the Scotch universities, and it is in vain to endeavour to repeat the old cry of the Scotch universities standing in the way. Our system is one to be followed, not to be decried and interfered with on account of the interests or jealousies of London corporations, or to suit the notions of English universities, which have done little for medical education in the past, and cannot do much for it in the future. Look at the boasted English Conjoint Scheme of 1878, the outcome of some seventy conferences, with its sixteen apothecaries on the examining board, and not a single examiner from the universities, although it was put forward as a scheme which included the universities. That is the kind of joint board we may expect from a council in which English votes predominate. That the present system of registration on incomplete qualifications ought to cease no one can hold more strongly than I do, but in the granting of such qualifications the Scotch universities have ceased to have any part. If the jealousies or interests of corporations continue to prevent their combining to form a joint examination in each metropolis, they must be made to do so by the strong hand of the law, but in doing so it is neither necessary nor just to harass the students of our universities with

additional examinations, or to lay expense on them, because London corporations require a certain sum of money, or for the sake of the name without the reality of uniformity. The Scottish universities, while ready to render every help to apply remedies which are required in the public interest, will doubtless feel it to be their duty to endeavour to prevent all such impositions being placed on the large body of students whom they educate.

It is in vain for our English friends to try to revive the cry that the Scotch universities stand in the way. That cry did duty some years ago till its hollowness was exposed, and the guns of the London corporations and English universities were turned against themselves. Let our English friends rather come to Scotland and see how thoroughly its universities teach and examine, and try to follow our example if they can.

I am, Sir, yours faithfully,

Aberdeen University, December 9th, 1882. JOHN STRUTHERS.

To the Editor of THE LANCET.

SIR,—While acknowledging, as in duty bound, your very paternal advice and warning to the Scottish universities on the basis of my letter to Dr. Glover, I think it is none the less necessary to remark that they will be extremely ill-advised (in my opinion), if they allow themselves, to be led by you prematurely, either to approve or to resist medical legislation, which is, as yet, in the future. When the Bill, which is expected and desired from Lord Carlingford and Mr. Mundella is actually before us, the universities will no doubt consider it, both as to principles and details, with every desire to aid in the settlement of a long-vexed question. Therefore I cannot help thinking that the heading you prefix to my letter, "The Opposition of the Scottish universities to Medical Legislation," is, so far, misleading, and is not borne out by anything in the letter itself. The deputation to the Lord President in several points, as I believe, misrepresented the existing state of opinion in Scotland; and I took the opportunity, while correcting a positive error of statement as regards myself, to enter a caveat against these more general, and, to me, very palpable, misrepresentations. Lord Carlingford, indeed, made, as regards some of these, the very judicious remark: "Scotland is a country that will always make its voice heard." The Lord President of the Privy Council, in 1878, in Committee on the passing his Bill of that date through the House of Lords, unfortunately placed himself entirely in the hands of advisers who were considered in Scotland to be adverse to the opinion of the Scottish universities, and much of the feeling of "opposition" to which you allude may be traced to that fact. The Scottish universities are, as THE LANCET freely admits, in charge of an educational interest equal to that of all the London schools put together, and it is out of the question to suppose that they are to refrain from opposing whatever they may regard as injurious to that great interest. They may possibly prefer, as I do, the scheme of Professor Huxley, or that of Professor Turner, to that contained in the report itself; but they are not on this account "opposed to any well-considered legislation," or subject to the imputations contained in your leading article as regards their motives. Let me add, that they are very sensible of the evident care and consideration given to the whole difficult subject by the late Royal Commission.

I am, Sir, yours truly,

Glasgow, Dec. 12th, 1882.

W. T. GAIRDNER.

### "PICRIC ACID AND SUGAR TESTING."

To the Editor of THE LANCET.

SIR,—I am quite ready to leave the subject of picric acid and sugar testing in the hands of Dr. Johnson, and should not have troubled you with a further communication did I not feel that his remarks about sulphides in relation to the urine call for a rejoinder.

Dr. Johnson says, "But Dr. Pavy, in his letter, goes on to state that 'sulphides of ammonium and potassium are capable of being generated by boiling urine with potash.' This, so far as regards normal urine, I am told by much better chemists than myself is an improbability, and cannot be accepted upon the mere *ipse dixit* even of so great an

authority as Dr. Pavy." Whilst writing this last passage Dr. Johnson's memory must have failed him in the literature of the subject, or his pen for the moment been permitted to run wild. The statement is nothing more nor less than what is to be found in standard works referring to the chemistry of the urine. Simply looking at the books which happen to be before me on my shelves, I find that Parke, Sausderson, Kirkes, Odling, and the late Dr. Golding Bird all speak of a certain amount of unoxidised sulphur existing in the extractives of the urine. This, in other words, means the capacity for producing a sulphide on boiling with potash. Neubauer and Vogel go further, and say, "Sulphuretted hydrogen is sometimes, though very rarely, found in the urine. Its presence is readily ascertained by its property of blackening paper moistened with a solution of sugar of lead." They "had once an opportunity of examining for a length of time urine which contained sulphuretted hydrogen; it was periodically secreted by a man whose lower extremities were paralysed through gout." They suggest even that sulphuretted hydrogen may be sometimes formed by a reduction of sulphates, and say, "It has been already stated under the head of sulphuric acid, that sulphates, when exposed to a moderately high temperature, in contact with organic substances, soon give rise to the formation of sulphuretted hydrogen; and in this way we may, perhaps, account for its formation in the urine."

Next, Dr. Johnson says: "He [Dr. Pavy] further states, 'that a sulphide is actually produced by the action of potash upon healthy urine is shown by the well-known fallacy that Moore's, or the liquor potassæ, test is open to from the presence of a little lead.' I confess that this statement surprises me not a little." Again, a statement which thus gives surprise to Dr. Johnson is to be found in textbooks under the head of "Moore's Test." The late Dr. Golding Bird, in his work on "Urinary Depositions," says: "Dr. Rees has drawn attention to an important error which may arise in the indications of this test [Moore's] from the solution of potash employed containing lead. When this is the case the sulphur in the urinary excretion produces a dark colour with the lead, and might lead to a suspicion of the presence of sugar where none exists." Dr. Odling, in his work on "Practical Chemistry," says: "Moreover, caustic potash frequently contains lead; and this impure reagent, acting upon the sulphur of the ordinary urine, or more decidedly in albuminous specimens, will occasion a brown discolouration." My own observation confirms these statements, notwithstanding Dr. Johnson says, "It has often happened to me in boiling albuminous urine with liquor potassæ to find the liquid darkened and a subsequent precipitate of sulphide of lead, the sulphur being a constituent part of the albumen and the lead an impurity of the potash; but I have never observed this change to occur in healthy urine." The fact is, everything depends upon the delicacy or roughness with which the observation is carried out, and with healthy urine the production of sulphide of lead is easily susceptible of demonstration. Naturally, with albuminous urine, the albumen forming a source of sulphur in addition to that due to the extractives, a much more marked result is observed. If a couple of test tubes be taken and a small quantity of a solution of potash be placed in each, and to one a little acetate of lead be added, we shall have a representation of Moore's test in a proper state and contaminated with lead. If now some concentrated (I do not mean artificially concentrated) healthy urine be added in equal quantity to each, and the two be boiled for a short time, no difficulty will be experienced on looking at the two tubes side by side in seeing a colouration due to the formation of sulphide of lead. The amount of colouration varies according to the degree of concentration of the urine or the amount of extractives present, and in medium or low specific gravity specimens the effect may not be sufficiently marked to be perceptible.

I am, Sir, your obedient servant,

Grosvenor-street, Dec. 12th, 1882.

F. W. PAVY.

To the Editor of THE LANCET.

SIR,—In my letter to you last week I omitted to reply to Dr. Pavy's suggestion, that in my "original observation on the two specimens of albuminous urine the albumen had something to answer for in the result." The result of the following simple and easily repeated experiment negatives that idea. A specimen of urine containing as much albumen

as, when coagulated, occupied one-fourth the column of urine, was freed from albumen by filtering after the coagulation of the albumen by boiling. The filtrate, after the separation of the albumen, and a portion of the highly albuminous urine were then tested separately, but in precisely the same way, by boiling with potash and picric acid, and with results perfectly identical. The colour in the two test tubes was indistinguishable. The presence of the albumen did not increase or appreciably modify the reaction with picric acid and potash. This result is in accordance with my son's more elaborate observations on the effect of mixing a sulphide with the urine, and described in his letter to you.

After comparing the effect of the picric acid and potash test on the urine before and after the removal of the albumen, I tried the experiment of boiling with potash and a few drops of solution of lead. The contrast was very striking, for while the albuminous urine was speedily blackened by sulphide of lead, the urine which had been freed from albumen underwent only that slight deepening of colour which usually occurs in normal urine when boiled for a minute or two with liquor potassæ. It appears, then, that the presence of sulphur, in combination with albumen in the urine, in no way interferes with the picric acid and potash test for sugar. It is therefore unnecessary to separate the albumen before testing for sugar in this way, although the separation is necessary before testing with Fehling's solution, which would otherwise be decomposed by the sulphur in the albumen.

I am, Sir, yours faithfully,

Saville-row, Dec. 11th, 1882.

GEORGE JOHNSON.

To the Editor of THE LANCET.

SIR,—In his letter in your issue of Dec. 2nd, Dr. Pavy seems to conclude that the colour produced by boiling picrate of potash solution with potash alone is the same as that produced by sugar, and he says that I confirm him in that statement. It is true that a certain amount of red colouration is observed, even when no sugar is present; but I have made an observation during the last week which proves that this colour is not due to the same cause as that which is seen on boiling with saccharine liquids. If a little solution of starch be added to the alkaline picrate test, and the mixture boiled, no red colour is developed, the liquid remaining yellow; but on introducing some sugar solution and boiling, the characteristic red tint is at once produced. It is quite probable that this inhibiting action of the starch will considerably increase the delicacy of the test, since it enables us to start with a more nearly colourless solution.

As regards the action of alkaline sulphides upon alkaline picrate, there is no doubt that the colour produced by these salts on boiling their solutions with potash and picrate of potash is identical with that produced by grape sugar in the same circumstances, and the test appears to be as delicate for alkaline sulphide as for sugar. But Dr. Pavy makes a bold assertion, quite unsupported by experimental evidence, when he says that "a sulphide is actually produced by the action of potash upon the constituents of healthy urine;" for the only evidence he quotes appears to be of doubtful accuracy, the darkening of the urine by liquor potassæ in presence of lead being only observed in the case of albuminous specimens.

I have made a series of experiments, which have led me to the belief that (1) no alkaline sulphide is formed when healthy urine is boiled for some time with liquor potassæ, and (2) that even if a trace of alkaline sulphide were produced, it would not in any way interfere with the application of the picrate test for grape sugar to the urine containing it.

The method of experimentation employed will be sufficiently illustrated by the following example:—Twelve fluid ounces of normal urine, perfectly free from albumen, but producing the usual red colouration on boiling with alkaline picrate, were mixed with six fluid ounces of a 2 per cent. solution of potash, and the mixture boiled down to eight fluid ounces. The concentrated alkaline liquid was now made up to twelve fluid ounces (the volume of the original urine) with distilled water. On testing with picrate and boiling, not the slightest darkening of tint could be perceived beyond the slight reddish colour yielded by the picrate itself, a solution containing the same quantity of picrate and of potash being boiled at the same time in a separate tube and used for comparison. Moreover, the addition of nitroprusside of sodium solution to another portion of the alkaline

urine gave no indication of the presence of sulphide, though the absence of any substance interfering with the reaction was proved by adding a drop of an aqueous solution of sulphuretted hydrogen gas to the alkaline liquid containing nitroprusside, when a deep colouration was at once produced. On adding a little  $H_2S$  water to the alkaline urine (boiled as above), containing picrate and again boiling, no red colour was observed, though lead acetate produced a dense black precipitate in the liquid; and, indeed, a considerable quantity of sulphide must be added to alkaline urine before any indication can be obtained of its presence by the picrate test, though this test is excessively delicate when applied to pure solutions of alkaline sulphides.

The explanation of the above results is self-evident to any chemist. It is well known that solutions of glucose are easily decomposed by boiling even with dilute alkalies. It is also well known that there are unoxidised sulphur compounds in healthy urine. Dr. Pavy suggests that these sulphur compounds may be converted by boiling with potash into alkaline sulphide, which may in its turn give a colour when boiled with picrate identical with that produced by sugar. If Dr. Pavy's suggestion were correct, we should expect to find the concentrated alkaline solution giving distinct evidence of sulphide with the picrate test, whereas it gives no indication at all. In short, so far from any compound being formed by boiling the healthy urine with potash, which gives a red colour with picrate, the substance or substances which do give this colouration are destroyed altogether by such treatment; and, as grape sugar is similarly disintegrated, the result of this further investigation has been to add an additional confirmation to Brücke's original statement, that small quantities of grape sugar are present in healthy human urine.

I am, Sir, yours truly,

King's College, Dec. 4th, 1882. G. STILLINGFLEET JOHNSON.

## DIPHTHERIA AND TYPHOID.

To the Editor of THE LANCET.

SIR,—Will you permit me as a pupil, and, in an humble way, coadjutor, of William Budd—of revered memory in medical science—in the investigations which first led to the recognition of the nature of typhoid and its mode of communication, and in the experiments that far-sighted and indefatigable pathologist made with regard to the nature and propagation of diphtheria and the kindred diseases, to point out that there is no such rarity as you suggest in the co-existence of the two maladies. As a matter of clinical fact—a fact too commonly overlooked, if, indeed, it be widely recognised,—typhoid fever is generally preceded by an affection of the throat, which if minutely examined will be found to be characterised by the presence of minute pellicles of diphtheritic membrane, usually situated on the upper and posterior surfaces of the tonsils, and nearly always accompanied by a few small patches in the fauces. This is particularly noticeable in the Paris fever. There would seem to be a tendency to the development of this membrane, in direct proportion to the intensity of the poison and the vigour of the "constitution"—if I may use this term—of the patient attacked, and in inverse proportion to the rapidity with which the glands of the intestine are infected. To state the results of inquiry—somewhat too dogmatically perhaps,—it may be said when a patient is infected by the specific morbidities of diphtheria or typhoid, the poison being the same in either case, it depends on the subject more than the disease whether the malady will take the form of "diphtheria," conventionally so-called, or of "typhoid fever." And in a case such as that on which you comment this week, in which the diphtheritic throat affection was strongly marked at the outset, there would, and probably will, be special danger of hæmorrhage; not from deep ulceration, but from the rupture of minute vessels in the course of the disease, when the diphtheritic sloughs are thrown off from Peyer's patches; the hæmorrhage, if it occur, being preceded by the appearance of exceedingly minute streakings of bright blood in the yellow-ochre-like (Budd) portions of the stools.

Another point of interest which I should like to mention relates to the susceptibility of patients to diphtheria and typhoid fever respectively. I believe the two maladies are so related that one may be employed—or will probably hereafter

be employed—as a prophylactic of the other. Experiments made on monkeys in the days before the "anti-vivisection" craze—that most pernicious bane of science—showed that the malady might be produced in a very mild form by direct inoculation; and, except that the amount of evidence collected was not sufficient for the absolute proof, that when once the organism had been infected with diphtheria it was not likely to have typhoid badly. I have now in recollection cases of the kind in which infection with typhoid subsequent to the infection of diphtheria was sufficiently distinct to cause the subject to communicate the typhoid to other subjects who had the malady fully developed, but only to show the symptoms of typhoid in its own case in a very mild degree.

There is therefore no reason why diphtheria and typhoid should not co-exist, not, as you assume, as two distinct diseases, but as one and the same disease in two forms. It is not rare to find these two forms together; but the throat affection is very commonly overlooked. The non-recognition of typhoid in the case of Mr. Fawcett probably arose from the delay which occurred, and which commonly happens, in the discovery of the "spots" in cases in which the diphtheritic throat affection is strongly developed, as a prodromic disease. The "spots" of typhoid, if we disregard for the moment the Irish type of the fever, must be considered as bearing a direct relation to the degree of the intestinal affection—I mean the degree of the disturbance set up in Peyer's patches in what may be called the eruptive stage of the disorder. Those who treat diphtheria would confer a benefit on the science of pathology—the pathology of existing disease—if they would in all cases look for typhoid spots. I believe there is generally some, though not great, irritation of Peyer's glands in diphtheria, and when this is strongly marked there ought to be "spots."

I am, Sir, yours faithfully,

Welbeck-street, W., Dec. 9th, 1882. J. MORTIMER GRANVILLE.

To the Editor of THE LANCET.

SIR,—The illness of the Postmaster-General has raised the question of the co-existence of diphtheria and typhoid fever, and which, from the general consent on this point of the medical journals, must be considered to be of rare occurrence. It may, therefore, be thought right that I should at the present time put on record the following case, which occurred in my practice:—

M. B—, a housemaid in a family living in the neighbouring village of Aston Clinton, was, after a week or ten days of general malaise and aversion to work, on December 12th, 1881, seized with a rigor, which was quickly followed by great heat of skin, excessive pain in the head, spine, and legs, extreme restlessness, and slight delirium, symptoms leading to the belief that it was a case of cerebro-spinal meningitis. In a few days this highly excited state of the nervous system having somewhat subsided, soreness of throat, with slight swelling of the cervical glands, was complained of, and patches of diphtheritic membrane were discovered on the uvula, soft palate, and tonsils. About the end of the week the patches had separated and peeled off; and the bowels, which up to this time had been sluggish, began to act more freely. A dull, heavy state, with much despondency, now supervened, and on examination rose spots were discovered on the chest and abdomen. The case was now clearly one of typhoid fever. From this time the patient progressed favourably, diarrhoea being controlled by scruple doses of the carbonate of bismuth, given in warm milk, until January 21st, 1882, when numerous spots of purpura with ecchymoses, the result of slight pressure, appeared, more especially on the arms and legs; and on the 23rd I found there had been, during the night, a very considerable oozing of blood from the gum adjacent to the stump of a carious tooth. This bleeding was with great difficulty arrested by pressure made with pieces of lint steeped in the strong solution of the perchloride of iron, but for several days it continued to recur. There was, too, considerable hæmorrhage from the bowels, and also from the vagina, to restrain which frequent doses of the tincture of perchloride of iron, with liquid extract of ergot, were given. After being reduced to the most extreme state of anæmia, the girl eventually recovered, and left for her home in Kent on the 6th of March.

The case is interesting, as showing the extreme difficulty

of forming a correct diagnosis in the early stage of typhoid fever. To give an opinion that a case is one of cerebro-spinal meningitis, then of diphtheria, and ultimately of typhoid fever, is, to say the least, embarrassing, and likely to be productive of a loss of confidence in the professional acumen, more especially in young practitioners.

I am, Sir, your obedient servant,

Tring, Dec. 11th, 1882.

EDWARD POPE.

### "THE DISCOVERY OF TRICHINA SPIRALIS."

To the Editor of THE LANCET.

SIR,—Our great anatomist does himself injustice. He speaks slightly of the "mere zoological elucidation of a species," yet it was on this very point that Sir James Paget generously went out of his way to remark that Professor Owen's "admirable memoir" was "much more complete and exact in zoological detail than anything he himself could have written." The concession was too liberal. Most foreign writers have remarked upon the "incompleteness" of Prof. Owen's record. Leuckart has a long comment to that effect. Kestner says: "The illustrious naturalist gave a very imperfect description of the parasite;" and the same author has made observations on Dr. Arthur Farre's more complete description. It comes to this, that in the matter of zoological status, the position assigned by Prof. Owen to the worm was altogether at variance with the facts observed by Paget and Farre—facts of organisation not observed by himself, although he was, as we are now told, so much "concerned in the working out of the evidences of the structure and zoological position" of the parasite. Mr. Hilton's guess placed the worm-specks within the helminths, and thus Hilton's conjectural allocation came nearer to the zoological truth than Prof. Owen's deliberate opinion, since, to employ Leuckart's words, Prof. Owen thought that the worm "agreed with the helminths only in its mode of life." As Prof. Owen's memoir gave a great impulse to the study of parasites, and as Leuckart has said "der Genusname Trichina (Owen) verbleiben muss," it seems to me that such concessions—added to other stores of scientific capital, the greatness of which no one disputes—ought to satisfy our venerated countryman.

I am, Sir, yours truly,

London, Dec. 10th, 1882.

T. SPENCER COBBOLD.

### NEWCASTLE-ON-TYNE.

(From our own Correspondent.)

AT Gateshead the subject of lead-poisoning has again occupied the attention of the guardians, and the matter was stated to be under the consideration of the Home Secretary. It was proposed that the number of cases of lead-poisoning which come under the notice of the medical men and relieving officers should be reported to the Local Government Board monthly. It was stated that there were many cases of the lead affection in the workhouse at present, under the care of Dr. Cook, and unless there was some improvement in the lead manufacture the consequences would become very serious to the workers, and ultimately to the ratepayers. There is a good deal of disease now of a zymotic character in the mining and agricultural villages of Northumberland and Durham. At Hunstonworth, an outlying village in Durham, in the Weardale Union, there has been an outbreak of small-pox; the disease was first introduced by a farmer, who had been at Newcastle purchasing stock. It transpired at a meeting of the Weardale guardians that in one house eight persons were found in one bed, including five illegitimate children, three of whom were ill with small-pox. It was proposed to remove the patients to the workhouse hospital at Stanhope, but Dr. Livingstone very properly and successfully resisted this proposition. Apart from the cruelty of transporting patients along twelve miles of a moorland road, he pointed out the dangers as to infection in the more populous place, and showed how the cases could be more safely and successfully treated on the spot, due attention being given at the same time to isolation and disinfection in a temporary village hospital.

As regards the sanitary condition of Sunderland, the Town Council has held two special meetings, and received

the recommendations of the health officer (Mr. C. E. Harris), which I am told they are likely to adopt; the report in question goes to the root of the matter, and is a production of labour and much ability. It points forcibly to a more speedy removal of midden contents, a thorough examination of the condition of the sewers, an alteration in the sewer ventilation, the encouragement of the watercloset system of sewerage, a house-to-house inspection by the inspectors of nuisances, an increase in the number of inspectors of nuisances, of whom there are only two for a population of 120,000. The severity of the weather and measles considerably influenced the death-rate of last week. There were 81 deaths, which represent an annual death-rate of 35.4 per 1000 inhabitants. Measles affected the death-rate by 5.2. Of the total deaths 40 were children under five years, and 10 were sixty years and upwards. Among children measles was the greatest cause of mortality, proving fatal to 12, of whom 10 had not reached their fifth year. Half of these deaths occurred in Monkwearmouth.

At the Newcastle Infirmary, I was told the other day, there were 231 patients in the house; the revival of trade and manufactures would seem to augment the number of daily accidents, some of them of a very severe surgical nature. Some cases were admitted of burns lately which presented some unusual points of interest. The cases in question arose from an explosion in an ether distillery, and it was observed in the cases which ultimately did well that the superficial burns or scalds were not blistered, but red, and bleeding, while none of the patients suffered from shock. Mr. Jeaffreson has had some important operations in abdominal surgery. The last was the case of a patient about forty, with a large tumour supposed to be ovarian. After the usual incision and tapping, it was noted that the growth had very deep pelvic attachments; on removing these it was found adherent to the uterus, so much so that it was a moot point as to the removal of that organ; however, it was dissected off, and found to be a cystic sarcomatous tumour. The patient's life was in the balance for some hours, but she may be said to have recovered without a bad symptom. It is nearly three weeks since the operation, at which Drs. William Murray, Creaswell, Garson, and Williamson were present. Mr. Jeaffreson will soon present details of his cases.

As regards the health of Newcastle, there appears to be some increase in small-pox, typhus, and other zymotic diseases. While on this subject I regret to hear of the death from typhus of Mr. C. M. Goyder, at the early age of twenty-six. Mr. Goyder was for some time house-surgeon at our infirmary, but some short time ago he commenced private practice as successor to the late Dr. MacLachlan in this city, and he was making good way in his profession, until he was suddenly struck down with fever. We lately lost another young surgeon here from the same cause, Mr. R. W. Smith, who contracted the disease when visiting some dispensary patients. Another name well known to old students has disappeared from the roll of life in that of Mr. Thomas Craster, who died at the advanced age of eighty. Mr. Craster was connected with the Museum and Anatomical School since their institution. He was what is commonly known as "a character," he had a keen love of his work, and his knowledge of comparative and human anatomy was the wonder of all students, with whom, as well as with the lecturers, he was deservedly a great favourite. Most old students here have sat at the feet of "Tommy Craster," as he was familiarly, but not disrespectfully, called.

Newcastle-on-Tyne, December 13th, 1882.

### SCOTTISH NOTES.

(From our own Correspondent.)

As the ever-recurring storm leaves its sad traces along our coasts, the question of the avoidance of death through shipwreck possesses increasing interest. Along the east coast especially, the fishing fleet is subject to dangers which every year seem to claim a larger number of victims; and just at present the excitement caused by these frequent disasters is likely to lead to definite results. The provision of a harbour of refuge at some point on the east coast of Scotland is now looked upon as an absolute necessity by those interested in

our sailors and in shipping; but as usual, the wrangle has begun as to which place shall be so favoured, and it is just possible that local jealousies may afford those holding the national purse-strings a sufficient excuse for overlooking the subject altogether. The recent storms have further demonstrated the necessity for a larger number of life-boats being provided for the same rock-bound coast; an experiment very fully tested at Aberdeen would indicate, that when properly carried out, the spreading of oil over the surface of a raging sea is sufficient to so still the waters that vessels can easily pass over the dangerous bars found at the entrance of many of our harbours. Mr. Shields, of Perth, has pressed this subject with great assiduity, and his last efforts seem to be his most successful, while the fact that an officer from the Board of Trade was present shows that the authorities do not neglect the matter.

Mr. Murdoch, of Drumwhirn, Kirkcudbrightshire, died last week, having completed his hundredth year in October last. The interest always attaching to the death of a centenarian is intensified in this case by the fact that Mr. Murdoch was the last contemporary of the poet Burns, who had seen and conversed with our great national bard. When a boy it appears that the deceased had done a slight service to Burns, and the familiar and kindly pat on the head by which he was rewarded for the action proved a life-long subject of congratulation to one who till the last retained a great power of story-telling and a wonderful conviviality. His faculties were acute, and till within a fortnight of the end Mr. Murdoch enjoyed out-door exercise freely.

Dr. Andrew Wilson has completed his course of lectures at Perth, given under the direction of the Combe Trust. In the eight lectures many physiological subjects of great interest have been discussed; but the noteworthy fact in connexion with this and similar courses in Scotland is the enthusiasm with which they are supported by the public. The leading citizens, as well as the people generally, were fully represented, and testified to the great value and need of such instruction being rendered available. Only the other day, from the two extremes in the social scale, the cry was for a knowledge of sanitary laws; and the coincidence of Earl Rosebery and a poor woman in the slums of Edinburgh—the former as chairman to Professor MacLagan as Health Lecturer for the night, and the latter at a conference of a novel kind between philanthropists and the very lowest of the people—stating that what was most required for the welfare of the classes they severally represented was sanitary teaching, is worthy of record. Lord Rosebery suggested the wholesale distribution of sanitary tracts, a method of reaching the people recently recommended by THE LANCET. Such leaflets, written by men whose views would command confidence, and gratuitously distributed, would be of great service to the poor and ignorant.

Diphtheria is at present proving most fatal in Dundee. It appears that during October there were seven cases reported, and of these six died, while in November, of sixteen cases, no fewer than fourteen ended fatally. Dr. Anderson, the medical officer, attributed this excessive mortality to deficient drainage, and the sanitary inspector has been instructed to investigate the question in the different districts where the outbreaks have occurred. The statistics of this disease recorded by medical officers of health are useful to place opposite those of men who publish such long lists of successful cases as raise the question whether, after all, they were cases of diphtheria with which those sporadic gentlemen were called upon to deal.

After lengthened consideration the directors of the Dundee Infirmary have determined to devote a separate ward to the treatment of children's diseases, and that the ward shall simply form part of the infirmary managed by the general board. The scheme for a new, or, in any way, independent institution, has been wisely set aside; but any one desirous of naming and endowing a cot can do so by a subscription of £200. The directors do not consider it at all necessary that children should have special ward accommodation, but to prevent the foundation of a rival charity, and in deference to the feelings of those who have interested themselves in the matter, they have resolved upon the above step.

**VENTNOR CONSUMPTION HOSPITAL**—An anonymous donor has presented this institution with funds for an additional house and furniture to meet the great pressure of applicants for admission.

## NIGHT LECTURES.

(From a Correspondent.)

THE Council of the Royal College of Surgeons in Ireland have passed a resolution refusing for the future to receive certificates of night lectures. This decision, come to so unexpectedly and so late in the session, must prove a hardship to a large class of young men engaged in business during the day, who have not the time to attend lectures during that period, and who were in the habit of dissecting and attending the various courses of lectures in the evening. A man who can obtain his diploma under these circumstances deserves praise for his energy and perseverance. Of course it is a debateable question whether the ranks of the profession should be recruited from this source—that is to say, whether it is probable that men who are otherwise occupied during the day from pecuniary necessity, when admitted members of the profession are likely to add to its honour and dignity. Much may be said on both sides of the question, but what I consider as injudicious is the action of the Council in passing a resolution of the kind referred to, when a large number of students—in one school alone about fifty—have entered for night lectures, paid fees, and proceeded with professional work, on the understanding that their attendance on night lectures would be countenanced as heretofore. Some time ago a correspondence took place between one of the medical schools and the Council on this very subject; but the College, although objecting, did not positively refuse to receive certificates of night lectures, and gave no intimation that they would do so without proper notice. Of course it may be said that the hardship is only nominal, and that those affected by the resolution can go to other corporations; but if I am not misinformed, the Irish College will also decline to receive certificates of lectures from any school at which night lectures are given. If the Council had refused to receive certificates of night lectures after this year it would have been perfectly fair on their part, having given due notice, but under present circumstances the resolution appears oppressive and unjust.

## HYPNOTISM IN PARIS.

(From an occasional Correspondent.)

### NO. V.

I HAVE now gone through the different phases of animal magnetism or hypnotism, as it is now called, to give it a more scientific character, from the days of Mesmer up to the present time, and the different phenomena that may be produced in subjects during this state. These are the cataleptic state, the lethargic state, and the somnambulistic state. The demonstrations of Professor Charcot and Dr. Dumontpallier have hitherto been confined to hysterical and hystero-epileptic females, but we have seen that the same phenomena, whether simulated or not, have also been produced in male subjects. Different methods have also been employed to produce hypnotism. Mesmer and his followers resorted to certain manœuvres called "passes"; Braid enjoined the subject to fix his or her eyes on a bright object held above the forehead; and Professor Charcot hypnotised his patients by placing them before a bright light and asking them to fix their eyes on it. M. Donato, however, thought his own eyes quite sufficient to transmit the magnetic fluid, and did nothing but stare at his subjects to produce the hypnotic state. The great secret consists in the fixing the gaze of the subjects, the result being a peculiar nervous state called hypnotism, from its resemblance to a sort of sleep, and which is produced by a certain influence on the nervous system through the medium of the eyes, or through the imagination. That the magnetiser possessed any special influence himself has long ago been disproved, and, as the late Professor Broca, in commenting on this subject, asserted, "one does not magnetise subjects, the subjects magnetise themselves." There is some semblance of truth in this remark, but it would have been more correct to say that the subjects hypnotised

themselves, though even this does not properly express the real state they are thrown into. I may here briefly describe that state. The eyes of the subject being fixed on an object, the pupils contract at first, and then dilate. This dilatation increases to a considerable extent, then they have a tendency to fluctuate, and if at this moment the operator or anyone else advance the first two fingers of the right hand horizontally and slightly separated towards the eyes, the lids close involuntarily. If after a few seconds the limbs be raised they will remain in the position in which they were placed, and, in fact, the three states already described may be produced. The special senses, besides that of vision, and a certain portion of the mental faculties, become abnormally excited, the symptoms being somewhat similar to the primary effects of wine, opium, and alcohol. When these effects have reached a certain point they are followed by a degree of depression much greater than that observed in the torpor of natural sleep. Here the state of the special senses, and the action of the muscles, may be altered at the will of the operator by simply blowing on the organ or organs it is intended to excite, or on the muscles the operator would render pliable, and which previously had been in a state of cataleptic rigidity. After some rest the other senses return to their primitive state. As has been already observed, a subject once hypnotised has the faculty of hypnotising himself at pleasure by simply holding up his finger and looking fixedly at it, or even at any other object. When this is done only a few times, and after certain intervals, no ill effects may result to the health of the individual, but the operation cannot with impunity be repeated often, as has been amply proved by the communication made by M. Milne-Edwards to the Academy of Sciences already referred to.

The facility with which certain individuals are magnetised has no doubt induced mountebanks and others to turn it to good account for their own personal interest, at the expense of the public; but what is less easily explained is the necessity or utility of producing hypnotism or animal magnetism in hysterical patients in hospitals or elsewhere; for, as a means of diagnosis, it is of little if any value, as the hypnotic state can be so well simulated even by healthy subjects. To physicians and surgeons it is of no practical interest, and to the lay public it is even dangerous, as there are a great number of people already too disposed to believe in all that looks and sounds marvellous. Even as a source of amusement it is dangerous, and as a therapeutic agent it is perfectly useless. In a report submitted to the Academy of Sciences on the 26th of February, 1844, M. François Arago expressed himself thus: "After the experiments conscientiously instituted under the auspices of the Academy in 1784, that which is termed animal magnetism does not exist; that it has nothing that would point to a new force for study; and as to its therapeutic virtues for curing or relieving patients, there is nothing, in consequence, to be expected from it." In another report, Bailly declared that "animal magnetism might exist without being useful, but that it cannot be useful if it does not exist." These truths have the same force now as they had in 1844, for nothing new has been since discovered in it, and animal magnetism or hypnotism is at the present time what it was in the days of Mesmer, a gigantic imposture. It is now the fourth time since its discovery in 1766 that the monster has been brought before the public in this country, but why the French capital should always be selected for its exploits has often been a puzzle to me, unless it be that adventurers of all sorts meet with greater hospitality here, and the Parisians, who are, after all, cosmopolitan in their composition, representing as they do the *élite* and ruffians of all classes and professions of the entire population of the country, have an abnormal thirst for what they term "le progrès." They abhor the *status quo* as nature abhors a vacuum, and this I believe is the explanation of their revolutionary character.

To return to hypnotism in its various forms. That the three states so frequently referred to may exist spontaneously or result from certain morbid conditions of the brain and nervous system is everywhere admitted. With these we have nothing to do; they cannot be simulated, or rather they cannot be produced artificially; and those interested in the subject might read with advantage the remarkable memoir of Dr. Paul Richet, entitled "Etudes Cliniques sur l'Hystéro-épilepsie ou Grande Hystérie," an abstract of which lately appeared in THE LANCET. As for hypnotism, or animal magnetism, to show that its existence is a pure

hypothesis I cannot do better than quote the following lines from that excellent dictionary of medicine by Littré and Robin: "In fine, the interest that there may be in the study of magnetism depends, according to certain authors, on our habitual ignorance of all that concerns the physiology of the brain, and this interest is reduced simply to the establishment of the fact that it is easier to produce at first in any single individual than in a portion or the whole of an assembly such an intellectual state, that the data more or less vague obtained by the first are interpreted by the others in the sense in which or towards which it is desired to direct the attention. It is in such a disposition of the brain that is found the explanation of all the singular effects of magnetism, allowance being made for the jugglery by which it is surrounded, effects varying according to the practices of the magnetiser, or according to the credulity and the cerebral disposition of the magnetised." (*Vide* article "Somnambulism.")

## NEW YORK.

(From our Correspondent.)

As a commentary to my remarks relating to the Hôtel Dieu at Montreal, I may mention a remarkable and unfortunate circumstance which has occurred there since the date of my visit.

One morning the gardener, in walking across the garden, discovered the dead body of a man. Subsequent inquiry disclosed the fact that the remains were those of a patient who had precipitated himself from the window of a ward situated in one of the upper floors of the hospital. The discovery caused much excitement, and several of the nuns hastened to the spot. One of them, in making a short cut across a bed of vegetables, stumbled over the body of a woman who had also, during the previous night, thrown herself from one of the upper windows of the establishment. The most remarkable circumstance about the affair was that neither of the patients had been missed from the wards. Such evidence of mismanagement will, however, surprise no one who reads the description of the Hôtel Dieu in my last letter. I mentioned that the patients were hid behind the curtains of old-fashioned four-post bedsteads, and I also referred to the entire absence of any member of the medical staff, or the presence of a resident surgeon, the place being wholly given over to the charge of nurses.

The establishment of the Post-graduate College of New York appears to have suggested, or provoked, others to form a similar medical school on the same principle. Thus is announced the "New York Polyclinic," a school of practical medicine and surgery, situate at 214 and 216, East Thirty-fourth street, New York. The list of directors and the faculty comprise the names of some of the most eminent physicians and surgeons, and the organisation appears a strong one. I would desire the success of both of these schools; but the question arises, Is there room for both? The *Medical Record* takes the ground that the necessity for either hardly exists, suggesting to post-graduates a system of bedside instruction under proper management. The establishment of the second school appears to jeopardise the success of the first, or even both. The result may, however, prove otherwise, and perhaps friendly rivalry may stimulate all concerned to great efforts, which may end in the establishment of both schools on a solid basis. In any case, I presume that "the fittest" will survive.

Much attention has been given on this side of the Atlantic to Dr. Koch's discovery of the special form of bacillus found in tuberculosis. The forms described by Dr. Koch were found, but the theory of their being the active contagion was regarded as far from proved. A new light has been thrown on this matter by Dr. H. D. Schmidt of New Orleans, who at a recent meeting of the Pathological Society of that city gave the result of his tests of the value of Dr. Koch's discovery. Dr. Schmidt is said to have given special attention to this subject for some years, and therefore took great interest in Dr. Koch's researches, and at once put the theory to exhaustive tests. He claims to have demonstrated beyond doubt that the tuberculous bacillus of Koch is simply

a fatty crystal. The report states that "this result was obtained after long and arduous labour, in which the diseased organs of persons who had been affected with pulmonary consumption were minutely and carefully examined. Dr. Schmidt succeeded in tracing the crystals, which were similar in appearance to those discovered by Koch, and evidently the same. To determine their nature Dr. Schmidt subjected the crystals to the action of boiling ether, when they disappeared, proving that they were not germs or organisms." Dr. Schmidt is well known for his microscopical work, much of which has been printed in the journal of the Royal Microscopical Society. I therefore refer to the matter; but it seems hardly possible that Dr. Koch and others could have made such an egregious blunder. Dr. Schmidt says nothing about staining; fatty crystals would hardly take the stain of an aniline dye. From this I infer that Drs. Koch and Schmidt are working on different material.

Lieutenant Schwatcka has sent a long article to the *Medical Record*, of a quasi-medico-scientific character, explaining in detail some of his views on living matter, which will doubtless be gratefully received by the biologists of this and other countries. The article, however, contained much matter of interest relating to his experiences in the Arctic regions in combating that scourge of Arctic explorers, scurvy. Lieutenant Schwatcka travelled 500 miles beyond the reach of civilisation without supplies, and, let it be known at the English Admiralty, without an ounce of lime-juice. It is claimed by Lieutenant Schwatcka, and after his experience his opinion should be received with respect, that fresh vegetables, lime-juice, or other preparations of this nature, are not alone necessary, provided freshly killed animal food can be procured. He found that drinking the blood of animals just killed had a beneficial effect. He also suggests that even raw meat may be used with good results; in fact, anything alive or freshly killed, whether animal or vegetable, and not of a poisonous nature, should be eaten by those who are in a position to be exposed to the ravages of scurvy. Such was the plan adopted by Lieutenant Schwatcka during his eventful and interesting travels in the Arctic regions, with the result of bringing his men home in excellent health and condition. The valuable suggestions of Lieutenant Schwatcka are further confirmed by a letter to the *Medical Record* by Dr. E. F. Brush, who states that scurvy very often attacks the lumber men of Maine, U.S., who are in the habit of eating the large black ants found in the pine trees as a remedy when suffering from this disease. This additional confirmation of Lieutenant Schwatcka's experiences may induce naval authorities to modify their old views that an expedition in the Arctic regions without a supply of lime-juice must at once abandon further progress, and return to their base of supplies.

New York, Nov. 21st, 1882.

## MEDICAL TRIALS.

### HIGH COURT OF JUSTICE: CHANCERY DIVISION.

#### THE STRATFORD PROVIDENT DISPENSARY.

ON Thursday, November 23rd, 1882, at Lincoln's-inn, before Mr. Justice Kay, Mr. Rigby, Q.C., moved the Court on behalf of Dr. Herbert Davies of Finsbury-square, for an interim injunction to restrain Drs. J. A. H. Budgett and W. E. Richardson, and the Stratford Provident Dispensary, their servants, agents, assistants, and others, from issuing or publishing any circulars, forms, cards, or letters, with Dr. Davies' name thereon, or from otherwise representing him to be the consulting physician to the said dispensary. Mr. Rigby in support of the motion stated that so long ago as 1880 Dr. Davies' name was being used in the manner complained of without his knowledge or consent, and on his solicitors calling attention to it at that time, they received in reply a written apology from Dr. Budgett, stating that the act complained of was a clerical error and undertaking the act complained of was a clerical error and undertaking that such a thing should not occur again. In August of that year Dr. Davies, however, again discovered that his name was still being used in contravention of the undertaking and he therefore was compelled to take the present proceedings. The facts of the case being in evidence, his Lordship granted the injunction prayed for.

### PROPOSED COMBINED EXAMINATION BY THE ROYAL COLLEGES OF PHYSICIANS AND SURGEONS.

A FRESH start has been made in what may become a practical Conjoint Examination for England. On Thursday last the Council of the Royal College of Surgeons appointed seven delegates to meet and confer with a sub-committee of the Royal College of Physicians on the possibility of a combination of the two Colleges for the establishment of a complete conjoint medical and surgical examination. The qualifications of the members of the sub-committee afford sufficient guarantee that no pains or consideration will be spared to accomplish the object proposed. Mr. Spencer Wells (President), Messrs. John Marshall and Cooper Forster (Vice-presidents), Sir James Paget, Messrs. Erichsen, Savory, and Holmes, will represent the Royal College of Surgeons, and Sir William Jenner (President), Sir Risdon Bennett, Sir William Gull, and Drs. Acland, Sieveking, Ord, and Pitman, the Royal College of Physicians.

At the same meeting of the Council the retiring members of the Board of Examiners in Anatomy and Physiology—namely, Messrs. Power, Pick, Rivington, Baker, Lowne, Bellamy, M'Carthy, Langton, and Gerald Yeo—were re-elected for a further period of twelve months.

## Obituary.

### SIR THOMAS WATSON, BART.

TO the entire profession and to a very large portion of the public, from the Sovereign downwards, the death of this eminent physician, which occurred on the 11th instant, will be a source of deep sorrow. We purpose now to give a sketch of his very distinguished career.

Thomas Watson was born at Kentisbeare, in Devonshire, on the 7th March, 1792. He was educated at the Grammar School at Bury St. Edmunds, of which Dr. Malken was head master, where he was a contemporary of the late Bishop Blomfield, with whom he always retained an intimate friendship. On leaving Bury school he was entered as a pensioner in St. John's College, Cambridge, of which college his uncle, Mr. Catton, was then a resident Fellow. He graduated B.A. in 1815, being placed tenth in the list of wranglers, was elected a Fellow of his college in the following year, and became M.A. in 1818. According to the rules then in force at St. John's College, no Fellow could retain his Fellowship for more than a short time without being ordained. From this rule, however, two Fellows were exempted, one of whom was to study medicine. A vacancy having occurred he availed himself of it, and retained his Fellowship until he married in 1825. During his residence at Cambridge as Fellow of his college, a period of eight years, he took private pupils, many of whom (including, amongst others, the late Lord Auckland, Bishop of Bath and Wells, and Lord John Thynne) continued their friendship with him to the end of life. He served the office of junior proctor in the University of Cambridge in 1823 and 1824.

In 1820 and 1821 he attended the medical classes in Edinburgh, and in a letter to his sister dated from Edinburgh he speaks of his intention to return thence in a sloop as being more economical and allowing the carriage of an unlimited amount of luggage. During his residence at Cambridge he made the acquaintance of his future wife, a daughter of Edward Jones, Esq., of Brackley, in Northamptonshire, who, as a favourite niece of the Rev. Dr. William Turner, then Dean of Norwich and master of Pembroke College, was a frequent visitor to Pembroke Lodge. They were married in 1825 in St. Luke's Chapel in

Norwich Cathedral, and in the same year he took his M.D. degree. In the following year Dr. Watson was elected a Fellow of the College of Physicians, and in May, 1827, Physician to the Middlesex Hospital, an office which he continued to hold until November, 1843. For some years after he settled in London practice came very slowly, patients and fees were few, and he was not free from pecuniary cares and anxieties. In September, 1830, he had the great grief of losing his wife, who died suddenly three days after the birth of their second child. In a letter written to his sister a few days after this terrible blow occurs this characteristic sentence: "My business henceforward in this life must be to endeavour to train up the children as nearly as I can as she would have trained them, and so to live as to acquire, through God's blessing, a hope that we may all hereafter meet their poor mother in happiness."

At the opening of the medical school of King's College in the autumn of 1831 Dr. Watson was appointed Professor of Forensic Medicine, and what we believe to be his first contribution to medical literature appeared in the *Medical Gazette*, vol. ix., 1831, entitled, "Remarks on the Dissection of Bishop, and the Phenomena attending Death by Strangulation." Bishop had been hanged for the murder of an Italian organ boy, whose body he brought to the dissecting-room of King's College for sale. The late Professor Partridge had his suspicions excited, and gave the man Bishop into custody. He was tried and condemned, and after his execution his body was sent to King's College for dissection. After this Dr. Watson was a frequent contributor to the *Medical Gazette*. The same ninth volume contains clinical lectures "On Pulmonary Hæmorrhage and on Epilepsy." In the tenth volume there are the Lumsian lectures on "Hæmorrhage from the Stomach, Intestines, and Urinary Organs." In the thirteenth volume there is an admirable introductory lecture, delivered at the opening of the medical session at King's College. In the fifteenth volume appears a paper "On the Efficacy of the Vapour Bath in Cases of Diabetes." The sixteenth volume contains two lectures "On Rheumatism of the Heart," and a paper "On the Connexion of Hypertrophy of the Heart with Cerebral and Pulmonary Hemorrhage." In July, 1832, Dr. Watson accompanied Sir Walter Scott from London to Edinburgh on his last sad journey from Italy to Abbotsford. In "Lockhart's Life of Scott" it is stated that Dr. Watson went the whole way to Abbotsford with Sir Walter; but in a copy of the work which he gave his son Dr. Watson has written the following foot note: "This is a mistake of Mr. Lockhart's. I did not accompany Sir Walter to Abbotsford, but returned from Edinburgh to London."

In 1836, Dr. Watson was appointed Professor of Medicine at King's College, and he continued to hold this office until the spring of 1840, when, at the opening of the newly-founded King's College Hospital, he had to resign either his office of physician to the Middlesex Hospital or his chair at King's College, and he preferred to retain the former office. The resignation of his professorship, which was felt as a calamity by King's College, was attended with this great benefit to the entire profession and the public, that it led to the publication of his admirable lectures on the "Principles and Practice of Physic." The lectures were first published week by week in the *Medical Gazette*. The first lecture appeared on Sept. 25th, 1840 (vol. xxvii.); and the last of the series on Sept. 23rd, 1842 (vol. xxx). In the following year, 1843, they were collected and published in two volumes by Messrs. J. W. Parker and Son, West Strand; a second edition was called for in 1845; and a third in 1848. Two editions have since been published; one in 1857, and, lastly, the fifth in 1871.

The publication of these lectures, admirable as they were universally acknowledged to be, not less for the soundness of their teaching than for their lucid, elegant, and scholarly style, greatly increased the reputation of their author, acquired for him the well-merited title of the Cicero of English medicine, and led at once to a large extension of his practice. The well-known volumes had, for a number of years, probably a larger sale than any other similar work that has ever been published, and we have pleasure in recording here an anecdote illustrative of his publishers' liberality, which was related to us by Sir Thomas Watson. Mr. Parker one day called on him and said that the sale of his lectures, and the profit resulting therefrom, had so far exceeded his (the publisher's) anticipations, that he did not feel justified in sharing the profits equally with the author, according to the terms of their original agreement; he there-

fore proposed that the author should receive two-thirds of the profits, while the publisher retained one-third. And as a practical illustration of his generous intentions, he handed the author a cheque for twelve hundred pounds. This surely is an example of liberality not unworthy of imitation.

At the College of Physicians Dr. Watson held numerous offices before he was elected President. In 1827 he was Gulstonian Lecturer; in 1830-31 Lumsian Lecturer; in the years 1833, 1834, and 1835 he gave the College lectures on *Materia Medica*; he was Censor in 1828, 1837, and 1838; on the Council at various times between 1833 and 1868; From 1858 to 1860 he was the College representative on the Medical Council. In 1862 he was elected President, and he held that office for five successive years. The College would have gladly elected him for a sixth period of office; but he declined on the plea of advancing years, and at the annual meeting for the election of President, after referring in graceful terms to the Fellows who had died during the previous year, he bade the College, as their President, farewell in the following eloquent and characteristic words:—"It only remains that I should attempt to do that which I feel to be well-nigh impossible—to embody in any form of words that I can devise the deep and inextinguishable sense of gratitude with which my mind is full for that kindness and trust which have placed me, year by year, on five successive occasions, at the head of the College of Physicians; in other words, at the head of the medical profession in this great country. According to my estimation, already more than once expressed, there is no nobler position in medicine, whether I look before me and around me to the body of men from whom it comes, or backwards to the splendid list of names of those who have preceded me in the presidential chair—Linacre, Caius, Glisson, Sir William Browne, Pitcairn, Sir George Baker; these, to go no later, are but a few of the eminent men and sound scholars with whom it may well be deemed a proud distinction to have one's name in any way associated. But, besides this great and repeated honour—the greater because so repeated—I have much else to thank you for. I have to acknowledge your indulgence towards the many shortcomings of which I am but too conscious. I have to express my thanks for your constant support and counsel in all difficulties, for your unvarying courtesy and deference, for the friendships which my official intercourse with you has formed or strengthened, and most especially for that recent signal and touching evidence of your approbation and esteem shown by your wish to possess within your walls some pictorial remembrance of my unworthy person. Of this high and generous compliment I can never, while life and reason remain to me, be otherwise than most gratefully, and I hope pardonably, proud. Further, I have to rejoice that the happy lustrum during which I have presided over your affairs has been harmonious and peaceful—disturbed by no unseemly quarrels or serious differences among us—stained by no scandal arising within our proper body, and productive, through your exertions and self-sacrifices, of something at least of benefit to the common weal. If I find anything to regret it is that I have not taken larger advantage of the opportunity which you have confided to me of promoting the interests of the College, and of our useful and noble profession."

Still, I must cherish the hope that the College has suffered no abatement of its ancient dignity and renown through my occupation of the office, which I now respectfully render back into your hands. And so, without encroaching further upon your time and in redemption of the pledge which I gave you last year, I bid you, as your President, one and all, a cordial, affectionate, and final farewell."

The "pictorial remembrance" to which he refers is an admirable portrait by his old friend, George Richmond, which was subscribed for by a large number of the Fellows, and which is now amongst the most cherished treasures of the college. A replica is in possession of Sir Thomas Watson's family, and it has been successfully engraved by Samuel Cousins.

Dr. Watson was appointed Physician Extraordinary to the Queen in 1859, and in 1870 one of the Physicians in Ordinary. On the 9th December, 1861, he was summoned to attend the Prince Consort at Windsor in consultation with Sir James Clark, Sir Henry Holland, and Sir (then Dr.) William Jenner, and his attendance continued until the lamented death of the Prince on December 14th. In 1866 Dr. Watson was created a baronet, the honour having been offered to him, as he was informed by the then

Minister, Lord John Russell, by the express desire of His Majesty. Amongst other distinctions which were conferred upon the great physician, he was elected an Honorary Fellow of his old college, St. John's, at the same time as the late Sir John Herschell. He was Hon. D.C.L. in 1862; Hon. LL.D. Cambridge, 1864; and Hon. D. of King's and Queen's College of Physicians, Ireland, 1859, he was elected a Fellow of the Royal Society. Many years he was a most influential member of the Council of King's College, London. During the session 1858, Sir Thomas Watson was President of the Pathological Society. In 1868, he became the first President of the Clinical Society; and in his inaugural address he urged the Society, with his customary good sense and grace, the supreme importance of an endeavour to obtain the exactness of knowledge, and therefore more direct intelligent purpose, and more successful aim in what is the aim and object of all our labours—the application of remedies for the cure and relief of disease.

During the last ten or twelve years of his life he had retired from the active practice of his profession, but continued to take great interest in all that concerned it.

Notwithstanding his advanced age, he enjoyed his usual health, spending great part of the last summer and autumn with his daughter and his son's family, partly at Reigate and partly at his son's house, Reigate Lodge, Surrey. On Sunday, Oct. 22nd, he had attended the morning service, as usual, at the parish church. On attempting to rise from the table, after lunch, he made a sudden inclination towards the left side, and would have fallen if he had not been supported by his son, who was standing by.

He afterwards took a short walk in the garden, but his left leg was found to be weakened, and he walked with great difficulty. He was seen at once by his neighbour, Dr. Lister, and on the following Wednesday he was visited by his old pupil and friend, Dr. George Johnson, to whom he calmly said, "This is the beginning of the end." There then came paralysis of the left leg and of the left side of foot and tongue, but there was no appreciable weakening of his arm. The mental faculties and the power of speech were quite unimpaired. Drs. Johnson and Walters were of opinion that there was probably obstruction by thrombosis of some of the smaller cerebral arteries.

On the following Thursday, Oct. 26th, after some exertion in walking across the room (up to this date he had been dressed daily and had gone downstairs), he was suddenly seized with difficulty of breathing, his face became cyanotic, and he believed himself to be dying. There appeared to have been some sudden failure of the heart's action; but the course of an hour or two the distress passed off. He was then carried to his bed; and from that day he did not leave his room, and rarely could even be moved from his bed. It was neither necessary nor desirable to dwell on the details of the subsequent seven weeks. The condition was one of increasing weakness and often of most distressing restlessness. Then there came irritation of the bladder with some retention, for which Dr. Walters was prepared to render the usual aid; but the restless sufferer, with a firm conviction that he had stone in the bladder, insisted on having Dr. Lister telegraphed for; and it was not until Mr. Lister had been sent for and had come a second time that he would allow Dr. Walters to give him the relief which henceforth was required two or three times daily.

During the last few weeks, a little milk with a small quantity of brandy was all the nourishment that could be taken. Weakness and emaciation, with a falling temperature, steadily increased. He retained his consciousness until within the last two days of his life, although his power of speech was latterly much impaired. It was believed that he understood and was gratified by a kind message of inquiry and sympathy from Her Majesty the Queen. He was often comforted by the reading of a prayer or a hymn.

At length he sank into a slumber, and so on Dec. 11th, near midnight came the final rest for which he had longed and prayed. To quote his own words with reference to his old and beloved friend, Dr. P. M. Latham, "Ripe in years as he was, and ready in spirit for the solemn change, his death must long be the subject of tender and sacred regret among the nearest and dearest of his surviving family and friends; nor will his memory soon cease to be reverently cherished throughout a much wider circle."

Throughout the trying seven weeks of weakness and of suffering Sir Thomas was most assiduously attended by his kind friend and neighbour, Dr. Walters, and occasionally by

Dr. Holman. He was also seen from time to time by his neighbour Dr. Greenhow, who was always ready to render assistance when needed, and he was frequently visited by Dr. George Johnson. We have already mentioned that Mr. Lister twice obeyed the distinguished sufferer's summons. It need scarcely be said that all felt it a privilege to minister to the relief of one so universally revered and beloved.

He has left instructions that his burial in the churchyard at Reigate, shall be conducted without pomp or senseless parade; and it has been arranged that the procession shall leave the house, Reigate Lodge, within five minutes' walk of the railway station, at half-past two this day (Friday), the 15th inst.

#### DEPUTY SURGEON-GENERAL PEARSON.

ON Nov. 20th the death was announced of Mr. Francis Pearson, Deputy Surgeon-General in the Indian Medical Service. Although his name was little known in England, it will long be remembered in Northern India as that of a man who rendered remarkable services to the State and to the public. For nearly thirty years Mr. Pearson, while performing at the same time other interesting but less important duties, was the chief officer in the vaccination department in the North-West Provinces. The history of his work would furnish to the scientific inquirer a collection of facts of extreme value on the whole subject of vaccination, for it is probable that no living man had in this respect greater opportunities for observation than those which Mr. Pearson enjoyed. He began his work about the year 1852 in the Himalayan Provinces of Gurwhal and Kumaon. There was, perhaps, at that time no country in the world in which small-pox was more prevalent or more fatal. Vaccination was hardly known, its advantages were disbelieved, and it was obstructed in every way by the ignorance and prejudices of the people. The Government resolved to check if possible the terrible mortality which was frequently occurring, and Mr. Pearson was appointed with a staff of vaccinators, the strength of which was gradually increased. Although it would have been easy for him to bring other influences to bear, he was wisely content to make vaccination popular by convincing the people that it afforded almost certain protection against small-pox. Before many years had elapsed he was rewarded by an astonishing measure of success. The people became convinced by their own observation that the protection was real; small-pox rapidly diminished, and at last virtually disappeared. Before Mr. Pearson left India, three years ago, small-pox, as an epidemic disease, had long been unknown in Kumaon and Gurwhal, and there was probably no country in Europe in which vaccination had become so universal. Many interesting stories could be told of Mr. Pearson's experiences, and to find a parallel to some of them we should have to go back almost to the time of Jenner. Not the least remarkable cases were those of the crucial experiment in which the professional and literary inoculators attempted in vain to inoculate children who had been successfully vaccinated. The great results obtained by Mr. Pearson in the hill districts induced the Government to extend his operations to the plains, and in 1864 he was appointed Superintendent General of Vaccination in the North-West Provinces. The extirpation of small-pox in so vast a tract, with a population of more than forty millions, was of course a work which will require the labour and care of many years for its completion; but before Mr. Pearson left India in 1879 immense progress had been made, and more than half a million of children were being successfully vaccinated in the North-West Provinces every year. Another interesting chapter in Mr. Pearson's life was the campaign he undertook against the mysterious and deadly disease known in the Himalayan Provinces as "mahamari"—i.e., "the great death." He proved conclusively that this was identical with true plague, and armed with official authority to enforce sanitary regulations he succeeded in completely eradicating it for many years in the district of Gurwhal. Space does not allow us to say more, but this notice of Mr. Pearson's career would be altogether deficient if it made no reference to those personal qualities which formed so strong an element not only in his social but in his official life. He was one of those fortunate men who command obedience and success, not merely by their ability and strength of character, but by

the personal affection and respect which everyone who knows them feels for them. He was buried at Kensal Green Cemetery on Nov. 24th, and many of his friends were present. Among them was Sir John Strachey, who had known him intimately from his youth, and on whom as member of the Government of India, and as Lieutenant Governor of the Provinces in which Mr. Pearson served, the duty had often fallen of acknowledging on behalf of the Government the admirable services which he had rendered.

## Medical News.

**ROYAL COLLEGE OF SURGEONS OF ENGLAND.**—The following Members, having passed the required examination for the Fellowship on the 23rd, 24th, and 25th ult., were, at a meeting of the Council held on Thursday last, duly admitted Fellows of the College:—

Buck, William Elgar, M.A., M.D. Cantab., Leicester; date of Membership Nov. 1872.  
Dingley, Allen, L.R.C.P. Lond., Argyle-square; July, 1878.  
Gunn, Robt. Marcus, M.B., C.M. Ed., Park-street; July, 1873.  
Hardie, Jas., M.D., L.R.C.S. Ed., Manchester; not a Member.  
Lane, Jas. Ernest, Norfolk-square; May, 1880.  
Prowse, Arthur Bancks, M.B. Lond., Cambridge; July, 1877.  
Smith, T. F. Hugh, L.S.A., Wimpole-street; Aug., 1877.  
Walters, Fred. Rufenacht, M.B. Lond., Croydon; April, 1880.

One other candidate passed the examination, but not having complied with the regulations of the College, will be admitted at a future meeting of the Council; and seven candidates failed to reach the required standard, and were referred for twelve months.

**UNIVERSITY OF LONDON.**—The following candidates have passed the recent M.B. (Honours) Examination:—

### MEDICINE. FIRST CLASS.

King, David Alex. (Scholarship and Gold Medal), St. Barth. Hosp.  
Wooldridge, Leonard C., D.Sc. (Gold Medal), Guy's Hospital.  
\*Harris, Thomas, Owens College.  
Collingwood, David, University College.  
Adeney, Edwin Leonard, Guy's Hospital.  
Wilkinson, William Camac, B.A. Sydney, University College.  
Honeyburne, Richard, L'pool Royal Infirm. and Univ. College.  
Webb, Malcolm, Owens College.

### SECOND CLASS.

Eq. { Buxton, Dudley Wilmot, University College.  
Shaw, Lauriston Elgie, Guy's Hospital.  
Fielden, William Eckett, Guy's Hospital.  
Eq. { Scharlieb, Mary Ann Dacomb, Madras Med. Coll. and Roy. Free Hosp.

### THIRD CLASS.

Pratt, Reginald, University College.  
Eq. { Batterham, John Williams, Westminster Hospital.  
Dingley, Edward Alfred, University College.  
Shove, Edith, London School of Medicine for Women.

### OBSTETRIC MEDICINE.

#### FIRST CLASS.

Scharlieb, Mary Ann Dacomb (Scholarship and Gold Medal), Madras Med. Coll. and Roy. Free Hosp.  
King, David Alex. (Gold Medal), St. Barthol. Hospital.  
Honeyburne, Richard, Liverpool Roy. Infirm. and Univ. Coll.

#### SECOND CLASS.

Shove, Edith, Lond. Sch. of Med. for Women.  
Dingley, Edward Alfred, University College.  
Harris, Thomas, Owens College.

### FORENSIC MEDICINE.

#### FIRST CLASS.

Wilkinson, W. Camac (Scholarship and Gold Medal), Univ. Coll.  
Webb, Malcolm (Gold Medal), Owens College.  
Maddison, Wm. Thomas, King's College.  
Wooldridge, Leonard Charles, Guy's Hospital.  
Currie, Oswald James, Guy's Hospital.  
Scharlieb, Mary Ann Dacomb, Madras Med. Coll. and Roy. Free Hosp.

#### SECOND CLASS.

Dingley, Edward Alfred, University College.  
Batterham, John Williams, Westminster Hospital.  
Adeney, Edwin Leonard, Guy's Hospital.  
King, David Alexander, St. Bartholomew's Hospital.  
Vinrace, John Hinks, Queen's Coll. Birm. and Univ. College.

#### THIRD CLASS.

Honeyburne, Richard, Liverpool Roy. Infirm. and Univ. Coll.  
Collingwood, David, University College.

\* Obtained the number of marks qualifying for a gold medal.

**UNIVERSITY OF OXFORD.**—At a congregation held on Dec. 7th the degree of M.D. was conferred on—

Joseph Arderne Ormerod, Jesus.  
Samuel Hatch West, Christ Church.

**UNIVERSITY OF CAMBRIDGE.**—At a congregation held on Dec. 7th the degree of M.D. was conferred on—  
William Collingridge, Christ's.

**UNIVERSITY OF DURHAM.**—At a convocation held on the 12th inst. the following degrees were conferred:—  
M.D. (practitioners of fifteen years).—P. Colmer, P. Cowen, R. Goddard, A. C. Rayner, and G. Thompson.  
M.D.—A. W. W. Dowding, T. Dutton, A. Mantle, G. L. Pardington.  
M.B.—D. H. Barley, F. W. Gilles, P. Brown, J. Hartley, W. Sheppard, M. S. C. H. Milburn, W. Sheppard.  
M.B. *ad eundem*.—Rev. R. R. Furlong, Trinity College.

**APOTHECARIES' HALL.**—The following gentlemen passed the examination in the Science and Practice of Medicine, and received certificates to practise, on Dec. 7th:—

Culhane, Francis John Fitzgerald, St. Helena, Hastings.  
Dobbs, Charles John, Newport, Isle of Wight.  
Hewitt, Frederick Wm., Grove-place, Pond-street.  
Maddison, Charles John, William-street, Regent's-park.  
Sparkes, Claud Stephen, St. Catherine, Guildford.  
Stephens, Samuel, Camborne, Cornwall.

The following gentleman also on the same day passed the Primary Professional Examination:—

Anwyl, James Norman, St. Bartholomew's Hospital.

It is proposed to increase the number of coroners for Surrey from three to five—two for the East, two for the West, and one for the Central Districts.

**WEST KENT MEDICO-CHIRURGICAL SOCIETY.**—The third meeting of the twenty-seventh session, 1882-83, was held at the Royal Kent Dispensary, Greenwich-road, on Dec. 1st, when Mr. H. W. Jackson read two papers, entitled, "Some Diseases and Injuries of Prehistoric Man," and "Royat in the Puy-de-Dôme as a Health Resort."

**FACTORY ACTS.**—At the County Petty Sessions, Faversham, Kent, on the 7th inst., Mr. J. A. Redgrave, Her Majesty's Inspector of Factories, appeared to prosecute the Cotton Powder Company (Limited) for having employed young men and women in their works on Sunday, Nov. 5th. One young man lost his hand through an explosion on the occasion. Penalties and costs amounting to £16 10s. were inflicted.

**HOSPITAL SATURDAY AND SUNDAY IN THE PROVINCES.**—At the annual meeting of the Shrewsbury Hospital Sunday Committee on Monday, it was stated that £288 5s. 3d. was collected in thirty-three places of worship, which was 15s. 6d. less than in the previous year; £142 10s. was given to the Salop Infirmary, and the remainder between the Eye and Ear Hospital and Dispensary.—Nearly £1000 has been received up to the 11th inst. by the Hospital Saturday Committee of Wolverhampton as the result of the annual contributions made by the artisans, shop assistants, and others, on the previous Saturday, in aid of the Wolverhampton and Staffordshire Hospital.

**WORKING MEN'S SEASIDE CONVALESCENT HOME.**—About eighteen months ago a movement was commenced to establish a Convalescent Home for Working Men in connexion with the Hospital Saturday Fund, which, however, was not to be touched for the purpose. About £320 has been subscribed, and it has been decided to purchase a large house at St. Margaret's, near Dover, which would accommodate thirty or forty patients. At a meeting held last week at Old Ford, to promote the enterprise, Mr. Hamilton Hoare said the bank with which he was connected had authorised him to promise the advance of whatever funds might be needed to purchase the site of the proposed Home, so that the project, which is an eminently worthy one, is not without promise of success.

**THE CAUSES AND PREVENTION OF BLINDNESS.**—The fifth International Congress of Hygiene, which will meet at the Hague, Holland, in 1884, will award the prize of £80 offered by the London Society for the Prevention of Blindness to the author of the best essay written in English, French, German, or Italian, on "The Causes of Blindness and the practical means for preventing it." Besides this prize, the International Society for the Improvement of the Condition of the Blind reserves to itself the right to award a second prize of £40, or two prizes of £20 each, and a silver gilt medal with a diploma, should it see fit, to such of the essays as should, in the opinion of the international jury for the principal prize, be deserving of it; the last-mentioned prizes will be distributed at the centenary festival of the first blind institution founded by Haüy, which will take place in Paris in 1884.

**YORKSHIRE POOR-LAW CONFERENCE (1882)**  
held on Thursday, Dec. 21st, commencing at 10.30 precisely, in the Masonic Hall, Halifax. After the President's address on "Recent (i.e., last session's) Poor-law tion," papers will be read on "The Education of House Children in Public Elementary Schools," by Messrs Bottomley; on "Settlement and Removal," by Mr. W. Wright; and on "Vaccination," by Mr. Dolan. Session will follow the reading of each paper.

**MANCHESTER MEDICO-ETHICAL ASSOCIATION.**—At a meeting of the above Association, held on the 8th inst., was introduced for discussion "The Position of Shipwrecked," and the following resolution was unanimously adopted:—"That this Association is convinced that the moral and sanitary departments of our mercantile marine are in a highly unsatisfactory condition, and that the lives of seamen are frequently endangered thereby. That this Association desires to press upon the Government the necessity of an immediate inquiry into the position, status, and efficiency of surgeons upon passenger ships."

## Medical Appointments.

Communications for this column must be sent DIRECT to the Office of THE LANCET before 9 o'clock on Thursday Morning at the latest.

**ANDERSON, BUSHELL, M.D.** Cantab., M.R.C.S., has been reappointed Medical Officer of Health for the Chesterton Rural Sanitary District.

**ANDERSON, J. W., M.B., B.S., 1st B.Sc.** Lond., M.R.C.S., L.S.A. Lond., has been appointed House-Surgeon to the Wolverhampton and Staffordshire General Hospital.

**ANDERSON, HENRY F., F.R.C.S.** Ed., has been appointed Surgeon to the "Apples" Nursery, Park-place, Clarence-gate.

**ANDERSON, WILLIAM J., M.B., L.R.C.S.**, has been appointed Surgeon to the Iron Works, Chester-le-Street.

**ANDERSON, G. E., M.R.C.S.**, has been appointed House-Surgeon to the Westminster Hospital.

**ANDERSON, M. CURSHAM, L.S.A.** Lond., has been reappointed Clinical Assistant to the Out-patient Department of the East London Hospital for Children.

**ANDERSON, RICHARD E., M.D.**, has been appointed Honorary Medical Officer to the Dover Hospital.

**ANDERSON, CHARLES OWEN, M.R.C.S., L.S.A.** Lond., has been appointed Assistant Resident Medical Officer to the London Fever Hospital, Abington.

**ANDERSON, WILLIAM HARRIS, M.R.C.S., L.S.A.** Lond., has been reappointed Medical Officer of Health for the Crediton Urban Sanitary District.

**ANDERSON, E. W., M.B., B.C.** Edin., L.R.C.P., has been appointed House-Physician to the Wolverhampton and Staffordshire General Hospital.

**ANDERSON, THOMAS, L.F.P.S.** Glas., L.R.C.P.E., has been appointed Medical Officer for the High District of the Pontefract Union.

**ANDERSON, CYRIL LLOYD, M.D.** Dub., M.B. Cantab., M.R.C.S., has been appointed Public Vaccinator for Christchurch and St. Saviour's District, St. Saviour's Union.

**ANDERSON, ROBERT GUY, L.K.Q.C.P.I., L.R.C.S.I.**, has been reappointed Medical Officer of Health for the Halstead Urban Sanitary District.

**ANDERSON, H., M.R.C.S.**, has been appointed Junior House-Physician to the Westminster Hospital.

**ANDERSON, TIMOTHY WOOD, M.R.C.S., L.S.A.** Lond., has been appointed Medical Officer to the Workhouse of the Thame Union, vice R. Lee, deceased.

**ANDERSON, JAMES M., M.R.C.S., L.R.C.P.** Ed., Senior Assistant-Physician to the Surrey County Asylum, Brookwood, has been appointed Medical Superintendent of the Surrey County Asylum, Cane-hill.

**ANDERSON, E. SETON, M.R.C.S., L.R.C.P.** Ed., L.M., has been appointed Medical Officer to St. Mark's Training College, Chelsea.

**ANDERSON, JAMES, M.D., C.M.** Aber., M.R.C.S., has been appointed Medical Officer for the Sandhurst District of the Berkhamstead Union.

**ANDERSON, R., B.A.** Oxon., M.R.C.S., has been appointed Senior House-Physician and Chloroformist to the Westminster Hospital.

**ANDERSON, ALEX. WILLIAMSON, M.B., C.M.** Ed., has been appointed Medical Officer for the High District of the Longton Union.

**ANDERSON, WALTER JOHN, M.D., C.M.** Ed., has been reappointed Medical Officer of Health for the Borough of Portsmouth.

**ANDERSON, H., M.R.C.S.**, has been appointed Medical Officer for the Christchurch District of St. Saviour's Union, vice T. S. Worboys, deceased.

**ANDERSON, J. H., M.K.Q.C.P.I., M.R.C.S.**, has been appointed Medical Officer for the Second District and Workhouse of the Guiltcross Union, vice Sayer, deceased.

**ANDERSON, CHARLES J., M.D.**, has been appointed Certifying Surgeon, under the Factory Act, for the Snodland District, vice T. L. Marsden, resigned.

**ANDERSON, ALFRED, M.R.C.S., L.S.A.** Lond., has been reappointed Medical Officer of Health for the Romford Rural and Urban Districts.

## Births, Marriages, and Deaths.

### BIRTHS.

**CAMERON.**—On the 10th inst., at Lochiel, Harlesden, N.W., the wife of Charles H. H. Cameron, L.R.C.P. Lond., M.R.C.S., prematurely, of a son, stillborn.

**CLARK.**—On the 15th ult., at Umritsar, Panjab, the wife of H. Martyn Clark, M.B., C.M. Edin., Medical Missionary of the Church Missionary Society, of a son.

**DAVISON.**—On the 12th inst., at Langton House, Battle, Sussex, the wife of Rashell Davison, M.D., of twins.

**EMERY-JONES.**—On the 5th inst., at St. John-street, Manchester, the wife of A. Emery-Jones, M.D. Edin., of a son.

**HUTCHINGS.**—On the 7th inst., at Southborough, Tanbridge-Wells, the wife of Edward J. Hutchings, M.R.C.S., of a son.

**LAMB.**—On the 8th inst., at Yew Tree Cottage, Lewisham, the wife of William Lamb, M.D., of a son.

**MANDERS.**—On the 5th inst., at Agincourt House, Yorktown, the wife of Horace Manders, F.R.C.S., of a son.

**RAYNER.**—On the 12th inst., at the County Asylum, Hanwell, the wife of H. Rayner, M.D., of a daughter.

**WALLIS.**—On the 10th inst., at Priory-place, Doncaster, the wife of Ferdinand Wallis, M.R.C.S., of a son.

### MARRIAGES.

**ANDREW-MARTIN.**—On Oct. 28th, at Christ Church, Mussooria, George Andrew, M.B., Surgeon-Major, A.M.D., to Milly, widow of the late Curtiss Martin, Brigade Surgeon, A.M.D.

**DRURY-YOUNG.**—On the 9th inst., at Holy Trinity Church, Bournemouth, William Vallancey Drury, M.D., of Lingmoor, Bournemouth, to Emelyn, eldest daughter of Edward Young, Esq., J.P., of Thornleigh, Bournemouth, and Birchfield, Lancashire.

**MACGEEGH-DAVIES.**—On the 6th inst., at Baltimore, U.S.A., by the Rev. Dr. Leeds, T. E. Foster MacGeagh, M.D., &c., eldest son of Benjamin Scott Foster MacGeagh, Esq., of Combe House, Coombe, Surrey, and the Middle Temple, London, to Fanny, daughter of the late S. D. Davies, Esq., of Baltimore, U.S.A., and niece of Sir W. Rose Robinson, K.C.S.I. (By cable.)

**SHARP-MORETON.**—On the 7th inst., at Bushbury Parish Church, by the Rev. George Tuthill, Vicar of St. Paul's, Wednesbury, assisted by the Rev. J. W. Kenworth, Curate in Charge, Gwinnett Sharp, Surgeon, of Walsall, to Elise, younger daughter of the late John Moreton, of Moseley Court, Wolverhampton.

**SWALE-PARISH.**—On the 5th inst., at St. Mary's, Guildford, Harold Swale, M.B. Lond., of Ingfield Hall, Settle, Yorkshire, and of Tavistock, Devon, to Alice, daughter of Capt. Parish, R.N.R. (late of P. and O. Co.'s Service), of Guildford.

**FRAMPTON-TURNER.**—On the 7th inst., at Holy Trinity, Paddington, Tom Henry Trevethan, M.R.C.S., elder son of Thomas Frampton, M.R.C.S., L.R.C.P., to Kate, third daughter of the late J. Turner, Esq., of Cleveland-square, Hyde-park.

**WELLS-WILLETT.**—On the 9th inst., at the Parish Church, West Brighton, Anne Maria, second daughter of the late R. B. Willett, Esq., of 20, St. John's-terrace, West Brighton, to Chas. Wells, M.D., M.R.C.S. Eng., L.S.A. Lond., of 13, College-crescent, Belairpark, N.W.

### DEATHS.

**BOUGLAS.**—On the 9th inst., at Carlisle, James Bouglas, L.F.P.S. Glas., aged 84.

**BENSON.**—On the 10th inst., at Bath, Ernest Walter Benson, B.A. Camb., L.S.A., M.R.C.S., youngest and beloved son of George Benson, Esq., Gloucester-street, Warwick-square, South Belgrave.

**BAYES.**—On the 8th inst., at Lansdowne-place, Brighton, suddenly, William Bayes, M.D., aged 59.

**ESWORTH.**—On the 12th inst., suddenly, from congestion of the lungs, at 11, Collingham-place, South Kensington, Alfred Esworth, F.R.C.S.E., aged 61.

**FOLKER.**—On the 1st inst., at Hanley, Staffordshire, Ellen Jane, wife of William Henry Folker, F.R.C.S., aged 52.

**FRANCIS.**—On the 10th inst., at Frederic-street, Sunderland, Matthew Francis, M.R.C.S., Surgeon to the Sunderland and River Wear Police.

**GIBBONS.**—On the 6th inst., at Waterloo-road, Dublin, Surgeon-General John Gibbons, Retired List, Companion of the Bath, and Chevalier de la Légion d'Honneur, late Surgeon of 44th, 95th Regiments, and Royal Artillery.

**RITCHIE.**—On the 30th ult., at Chesterhill House, Anstruther, N.B., the Rev. Wm. Ritchie, M.D., formerly of Berwick, Bovey Tracey, Liskeard, Plympton, and London, aged 82.

**SAVORY.**—On the 5th inst., at Wendover, Bucks, Arthur Henry Savory, M.R.C.S.E., L.R.C.P. Edin., youngest son of the late Joseph Thomas Savory, Surgeon, aged 34.

**WATSON.**—On the 11th inst., at Reigate Lodge, Surrey, Sir Thomas Watson, Bart., M.D., aged 90.

N.B.—A fee of 5s. is charged for the insertion of Notices of Births, Marriages, and Deaths.

## Notes, Short Comments, and Answers to Correspondents.

*It is especially requested that early intelligence of local events having a medical interest, or which it is desirable to bring under the notice of the profession, may be sent direct to this Office.*

*All communications relating to the editorial business of the journal must be addressed "To the Editor."*

*Lectures, original articles, and reports should be written on one side only of the paper.*

*Letters, whether intended for publication or private information, must be authenticated by the names and addresses of their writers, not necessarily for publication.*

*We cannot prescribe, or recommend practitioners.*

*Local papers containing reports or news-paragraphs should be marked.*

*Letters relating to the publication, sale, and advertising departments of THE LANCET to be addressed "To the Publisher."*

## AN IMPROVEMENT IN MERCURIAL THERMOMETERS.

MR. S. G. DENTON has recently exhibited at the Meteorological Society forty-six newly made mercurial thermometers, constructed in a special manner, the zero of which has remained constant for over twelve months. The thermometers comprised twenty-three standards and twenty-three clinicals. To prove that they were newly made, the pieces of enamel stems were sent to the Kew Observatory and hall-marked previous to having their bulbs blown. They were then constructed into thermometers, graduated, and returned to the observatory, and tested throughout. They were then placed under seal by the superintendent, and remained so for over a year, and after that time were again tested, the mean amount of change being only about half a tenth of a degree Fahr. A standard thermometer made by the same process as above was also shown, it having been verified in 1873 and in 1882; the zero was still constant.

## "ON THE INTERNAL ADMINISTRATION OF CHRYSOPHANIC ACID IN PSORIASIS."

To the Editor of THE LANCET.

SIR,—With reference to Mr. Cauty's communication on the above (THE LANCET, Dec. 2nd), I ask permission to draw attention to my paper, "Deductions from 319 observations of the action of chrysarobin—a new emetic purge," which was read before the Harveian Society of London in 1877, published in the *British Medical Journal* in May of that year, and published by Mr. Balmanno Squire in his "Chrysophanic Acid in Skin Diseases," in 1878.

Chrysarobin is the name by which freshly prepared Goa, Bahla, or Aroba powder is known. Chrysophanic acid, present in the proportion of 80 to 81 per cent. (Attfield), and resinous bodies (2 per cent.) having a similar action to the former, are the active principles of chrysarobin, or, as it may be less conveniently called, "yellow Aroba powder."

In the paper named I claim to have first observed the marked effect which chrysophanic acid has of discharging large quantities of bile from the body, foreshadowed its usefulness in small, repeated doses in cases of inactivity of the liver, and given such observations as I think enable the reader to deduce for himself the way in which small doses may be given so as to avoid the unpleasant effect which prevented continued medication with them in some of Mr. Cauty's cases. In large doses (ten to fifteen grains) I have found it a valuable emetic purge, which I should now be very unwilling to lose the use of.

I am, Sir, yours, &amp;c.,

J. ASHBURTON THOMPSON.

Thatched House Club, St. James's-street,  
Dec. 7th, 1882.

## MUSHROOM CATSUP.

A MICROSCOPICAL EXAMINATION of several samples of mushroom catsup has recently been made by a well-known fungologist, Mr. Worthington G. Smith, and has brought to light several details of its composition that must be highly pleasing to lovers of this condiment. Of four samples manufactured in London, in one he found only matter which looked like mashed up toast and salt; in another decayed fish, mildew, and broken twigs; in a third, fungus spawn, mildew spores, crushed walnut-husks, and vibriones, large black spores evidently belonging to the genus *coprinus*, and brown ones recognisable as those of the horse-mushroom. Genuine mushroom catsup should exhibit basidia, cystidia, and spores of the true mushroom, salt crystals, and occasionally a pollen grain or fragment of pappus, but nothing more.

## IMITATION BUTTERS.

OF these there are several kinds. *Butterine* is made by a respectable firm and of sound materials, and is a cheap and wholesome substitute for butter when this is dear. It is made, according to one receipt, by melting beef suet in warm water with carbonate of potash; then pressing out the oleo-margarine from the stearine, mixing the former with the soluble matter from cows' udders, a little annato, and a due proportion of milk, and then churning. *Bosh* is made by a direct admixture of various fats with (often very inferior) butter.

## THE TREATMENT OF UNUNITED FRACTURE.

To the Editor of THE LANCET.

SIR,—In the columns of THE LANCET of December 2nd, I see, on page 940, an account of a "case of ununited fracture of the humerus in an old man successfully treated by resecting the ends of the bones and fastening them together with a probe." Was not this operation severe, more especially so in an old "debilitated" man? On March 8th, 1884, a paper by Mr. Bickersteth was read before the Royal Medical and Chirurgical Society on the treatment of ununited fractures. In this paper he described a method of treatment by simply nailing the ununited ends of the bone together with a drill, which was then left in position by the removal of the handle. This without any resection, he it noted. The operation yielded the most satisfactory results. Since that date Mr. Bickersteth has further elaborated his method. I regret I cannot lay my hand upon the paper or reference to it. A sharp clean drill is taken, fitting into an Archimedean screw, and two or three pegs of ivory are carefully adapted to fit tightly into the drill hole, of suitable length, the upper ends to be slightly thicker than the lower. A small incision is made down upon the ununited ends of the bone, with all antiseptic precautions. The drill is passed into the bone in two directions, so as to nail both ends together; the drill is removed; the pegs are inserted, and driven completely home by a few taps of the mallet. The skin incision is closed, the wound dressed in the usual manner, and a suitable splint applied. On removing the dressing in about a week's time, the wound is found soundly healed. The pegs undergo changes consequent upon being tightly grasped by the living bone, and are not usually seen again. Firm union results. I can conceive it quite possible the operation might require repetition. In the cases that have come under my own observation no disturbance followed the slight operation.

I am, Sir, yours, &amp;c.,

W. T. C.

December 11th, 1882.

Dr. Ross, Mr. Louis Birch, and others.—The subject will not be overlooked.

## ECZEMA.

To the Editor of THE LANCET.

SIR,—Perhaps some of your correspondents can furnish a hint for the treatment of the following case:—

A gentleman, aged thirty-five, suffers yearly from an eruption of eczema on the backs of the hands and wrists which comes on when the weather gets warm, about the beginning of summer, and generally declines as the weather gets cooler, but recurs every year. He has many of the marks and appearances of the scrofulous habit, and there is an obscure history of gout in his family; but, with the exception of being rather nervous, he has nearly always had fair health. The remedies which seemed to have done most good are iron in large doses, arsenic, Easton's syrup, and lime-water, also milk diet and a bracing atmosphere, but nothing I have tried seems to prevent its recurrence in hot weather.

I remain, Sir, yours obediently,

MEDICUS.

December 12th, 1882.

M. T. G.—Writers of letters are responsible for the contents of their communications.

## SALICYLATE OF SODA IN SCARLATINA.

To the Editor of THE LANCET.

SIR,—There is an epidemic of scarlatina here of a severe character. I wish to record the very great benefit that seven cases have received by the prompt exhibition of salicylate of soda. I give it in doses of fifteen grains every two hours to adults until the ringing in the ears is produced, and then the dose is given every four hours during the first week. In all of my patients so treated the anginous symptoms have disappeared, and they have made good recoveries. For children I give one grain of the salicylate for every year of age of the patient.

I am, Sir, yours faithfully,

Scunthorpe, near Brigg, Dec. 11th, 1882.

JAMES COULDRY.

## FRIENDLY SOCIETIES MEDICAL ASSOCIATIONS.

*Justitia* says that an association of the above type is about to be started in a town of about 15,000, and asks our opinion, and that of our readers, on the subject. Our opinion is soon told. The existing Associations of this class have reduced the scale of remuneration for medical services, and disturbed far more respectable arrangements for medical attendance on the working classes and their families. They are not institutions that we can approve. They contemplate medical attendance on a monster scale for a miserable pittance that may attract a young and impecunious man, but should have no countenance from established and experienced members of the profession, and, we may add, a pittance that should not be offered by respectable working men to their medical advisers.

## INTERVENTION OF THE GERMAN GOVERNMENT IN THE CORPORAL DEVELOPMENT OF YOUTH.

ABOUT six months ago a society was established at Düsseldorf for the purpose of propagating in a systematic manner the generally received opinion that gymnastic exercises are of advantage to the corporal development of youth. Herr Von Gössler has issued a circular dwelling on the importance of suitable rooms and open spaces being provided for such exercises. He calls attention to the arrangements which he considers most suitable for carrying out the various suggestions which have been made by competent authorities from time to time as to the exercises most appropriate for the class of schools intended to be dealt with in the Government scheme.

## GLASGOW ROYAL INFIRMARY.

To the Editor of THE LANCET.

SIR,—In your issue of the 9th inst. there was a description of the New School of Medicine in connexion with the Royal Infirmary, Glasgow. In that account there is mention of a room set apart for "smoking, chatting, and reading." Now, to any person acquainted with students, such an arrangement shows a decided want of experience in organising a medical school, as smoking and chatting are not consistent with reading. On an average there are three hours per day not occupied by classes, which amounts to a good total at the end of the session; and if there was a suitable room this time could be profitably employed. The students have already asked the directors to remedy this defect, and apparently only the will is lacking, as there is a very suitable room, which at present is not used for any purpose, although ostensibly set apart for a surgical museum, for which object, according to the lecturer in surgery, it is wholly unsuitable. As THE LANCET at various times has been the means of causing improvements in medical matters, we hope, by our letter appearing in your columns, it may give the necessary stimulus to the directors to remedy a defect which seriously interferes with the studies of the students.

We are, Sir, yours, &c.,

December 12th, 1882. TWO ROYAL INFIRMARY STUDENTS.

*Ajax*.—Under the circumstances a minimum fee of ten guineas.

*Dr. Octavius Sturges*.—Yes.

## "ORCHITIS IN TYPHOID FEVER."

To the Editor of THE LANCET.

SIR,—Having read your very interesting article on the above subject in the issue of December 9th, I think you may like to have my personal experiences on the subject. About the middle of November, 1881, I had a mild attack of typhoid fever, and had become quite convalescent, having been out two or three times, when I had a sudden attack of orchitis, accompanied by extreme tenderness of both testes (phlebitis of external saphenous veins, or myalgia of scrotal muscles). The left testicle was the one affected particularly, and the pain was excruciating for about ten days when touched or pendant. After that I was obliged to suspend the testicles for three or four weeks, and they always ached after any extra exertion for a month or two afterwards. The scrotum was reddened; there was no urethral discharge. The epididymis was not especially involved, but the spermatic cord was tender for a short time, and the swelling was globular and about the size of a duck's egg.

I am, Sir, faithfully yours,

EDWARD P. MANLY.

Cambridge College, Cambridge, Dec. 12th, 1882.

*W. G.* should seek the advice of a qualified medical man.

*Dr. Harding*.—Too late for this week.

## ART. "GOITRE" IN QUAIN'S DICTIONARY.

To the Editor of THE LANCET.

SIR,—A letter appeared in THE LANCET of December 2nd, page 970, signed "Chirurgus," which questioned the correctness of some of the statements in my article on "Goitre." If the anonymous writer of that letter will publish his name, I will refer at length to his strictures. I may add that should my answer give satisfaction to the readers of the article on "Goitre," it probably will not give equal satisfaction to the surgeon who has written anonymously.

I am, Sir, yours faithfully,

POWELL THORNTON.

December 12th, 1882.

## THE EFFECT OF THE ELECTRIC LIGHT ON HEALTH.

THE above question was lately discussed at a meeting of the Hygienic Society of Hamburg, and Dr. Krüss explained his views on the subject at some length. He referred to the influence of the electric light on the human eyesight, and expressed his opinion that it produces no evil effects, the light having a violet tinge under most circumstances. He referred to the somewhat exaggerated expectations which had been formed as to the distance at which the light was visible at sea; but, on the whole, he considered that the safety of human life at sea had been increased by the use of the electric light in lighthouses. The electric light being free from the disadvantages incidental to the combustion of gas in the consumption of oxygen and the production of carbonic acid, he considered its development as being a hygienic measure of relative importance.

## THE CONSUMPTION OF TOBACCO.

THOSE who take part in the perennial crusade against tobacco, and all who disapprove of its excessive use, will be glad to learn that the consumption of tobacco is as small in England as in any other civilised country. From some statistics on the subject which have been published by a French journal, *Les Mondes*, it appears that in Russia, France, and England the consumption amounts to 1 lb. per inhabitant. In Italy it is rather higher, 1½ lb. Austria comes next with 2.25 lb. In the United States and Germany the consumption amounts to 3 lb., in Belgium to 4.5 lb., while Holland has the privilege of heading the list with a consumption per inhabitant of more than 5½ lb.

*Antigua*.—We have no knowledge of any respectable institution which grants degrees in medicine without examination, and we shall not pay our readers the poor compliment of asking them if they know such.

We are unable to find room this week for *Dr. Denkin's* communication.

*Subscriber*.—THE LANCET, vol. ii., 1861.

## PROFESSIONAL ETIQUETTE.

To the Editor of THE LANCET.

SIR,—A woman brought her little boy to me on Saturday evening, December 2nd. I prescribed for him, and told the mother he was too ill to be out; if not better, to let me know. They were staying at a farm bailiff's a short distance from the town, whom I had attended previously. On December 4th I was sent for to see the boy, and found him suffering from scarlatina. I wrote at once to the bailiff's employer, saying what the boy was suffering from, and advising him not to let his children go to the house. The next morning, on visiting my patient, I found Mr. Duke had been the previous evening, and Dr. Chessman, his partner, had preceded me that morning, and had gone away to get a room for my patient in the town, where he was moved in the course of the day from a lone house out of the town to a house in the middle of the town in a thoroughfare, without my consent—indeed, without any communication with me by the employer or his medical attendants (Duke and Chessman). I ought to mention that, as medical officer of health, at some inconvenience early in the day of the 4th I went to see my patient, with the intention of taking all proper measures to "stamp out" the disease which, being in a lone house, was in a most suitable place for so doing.

I am, Sir, yours, &c.,

Buckingham, Dec. 11th, 1882.

ROBERT DE'ATH.

*Dr. G. Stanley Murray*.—A medical man's claim would be on the friends. But the proprietor of an asylum is supposed to see that such claims are satisfied.

*Dr. Maurice G. Evans*.—Mr. Stamp, Great Portland-street, W.

## CASE OF FREQUENT TAPPING IN ASCITES.

To the Editor of THE LANCET.

SIR,—B. S.—, aged forty-two years (formerly a hospital nurse), was anxious that her case should be noticed in your valuable journal, and as it may interest some of your readers, I am glad to comply with her request. I may briefly state that the patient had been under treatment for many years at various times for congestion of the liver and stomach, and was eventually brought to death's door from an attack of violent hæmatemesis, from which she rallied slowly. The dropsy first showed itself during her recovery. Having diagnosed the case to be one of cirrhosis of the liver, I tapped her early, and removed about a gallon and a half of fluid on Jan. 8th, 1881. Between this date and Aug. 27th, 1882, I tapped her no less than thirty-nine times, and removed 110 gallons of fluid, the patient finally sinking from exhaustion on Sept. 7th. The treatment was merely palliative, the usual remedies for dropsy not suiting her. I used a cannula of small calibre, with india-rubber tubing attached, the process of tapping generally lasting an hour; and since it was so well borne, I was enabled to visit other patients in the interim. None of the directions mentioned in the text-books as to the use of compress and bandage were complied with, and the patient lay on her back or side, as she felt disposed. No post-mortem was made, as the nature of the case was evident.

I am, Sir, yours, &c.,

Edinburgh, Dec. 1882.

R. H. PATTERSON, M.R.C.S.

*A Twenty Years' Subscriber.*—1. There is no extra fee provided, under the Poor-law, for reducing strangulated hernia without the use of the knife. If the case were a very bad one, there could be no harm in a statement to the Board and an application for remuneration.—2. Rectified spirit is not so applicable to those practical purposes as the finer brandies, though, according to Sir Robert Christison, it is more free of grain oil than common spirits.—3. We think diagrams would not suffice for the examination referred to.

# Clinical Lecture

## CALCULUS IN THE FEMALE BLADDER.

*Delivered in University College Hospital,  
Oct. 23rd, 1882,*

By CHRISTOPHER HEATH, F.R.C.S.,  
HOLME PROFESSOR OF CLINICAL SURGERY.

GENTLEMEN,—You saw me last week remove from the bladder of a woman aged thirty-three the mass of calculous material which I show you in this bottle, and which weighs, now that it is dry, just one ounce. The patient is a married woman, and had been confined six weeks when she presented herself in the out-patient department, complaining of pain about the bladder and frequent micturition. For this she was sent upstairs to see me, and I had no difficulty in detecting a large mass of stone in the bladder. When placed upon the table in the lithotomy position, you saw that I proceeded to dilate the urethra with a pair of polypus forceps, and then introduced my little finger and subsequently my forefinger without difficulty. In this rapid dilatation there is of course some laceration, and it is usually upwards under the pubes, and does no harm. My finger enabled me to feel a very irregular mass of phosphatic stone, which I proceeded to break down with small lithotomy forceps, and I was able with these, with a scoop, and by washing out through a vulcanite speculum, to remove the debris which we have in the bottle. After clearing out all the fragments, I found that the bladder was in part encrusted with phosphates, and this mortar-like material I scraped away with the nail of the forefinger and a lithotomy scoop, until I was satisfied, by compressing the bladder with the other hand so as to sweep the finger over the whole interior of the viscus, that the mucous membrane was clear. Then, lastly, through the little vulcanite speculum, I applied a solution of nitrate of silver (a drachm to the ounce) over the whole surface of the interior of the bladder, and sent the patient to bed with a half-grain of morphia suppository in the rectum. I expected that there would have been more or less complete incontinence for a day or two, after which the patient would have recovered perfect control; but this was not the case. She was able to hold her water completely on the day of the operation, and passed from the first acid urine, instead of the abominably offensive ammoniacal urine which had been present before. Now, this I find the invariable result of mopping out the bladder with a strong solution of nitrate of silver; and some of you may remember a man in whom the same thing was seen after lithotomy. The woman is now taking her food well, and is fairly convalescent, so much so that I have allowed her baby to be put to her breast again.

The symptoms of stone in the female closely resemble those in the male, except that, from the close propinquity of the bladder to the uterus they may be referred to the latter organ. Frequent micturition, pain especially after emptying the bladder, with "bearing down," should direct attention to the bladder and the condition of urine, which last is probably thick, and may occasionally contain blood. The detection of a stone with the sound is comparatively easy, for the urethra is short, and there is no prostate behind which a small stone can lie hid, whilst the ease with which the fundus of the bladder can be simultaneously examined with the finger in the vagina makes the diagnosis simple enough.

Calculus in the female may be of renal or vesical origin, or both, just as in the male; but there is the peculiarity about stone in the female that it may occasionally have for its nucleus some foreign body introduced by the patient herself. If the foreign body is small, such as a piece of cork, and is completely enveloped by the calculous matter, it in no way complicates the treatment; but cases are not very uncommon in which a hairpin or some other implement has been introduced into the bladder, and having escaped the patient's grasp, has been left there to form the nucleus of a concretion which is certain to form. In these cases the foreign body projects from the stone, and may not improbably

have pierced the bladder, and given rise to serious complications.

Stone is not nearly so common in the female as in the male, the proportion between the two sexes being, according to Mr. Poland, one in the female to twenty or twenty-three in the male; and the same author remarks that "statistics respecting stone in the female, the operation and its consequences, and the mortality after operation, are incomplete and unsatisfactory." I am inclined to think, from what I have seen, that stone is more common in the female than is here stated, or than is generally supposed, because in all the cases I have had under my care the disease had not been recognised until shortly before I saw them, although the symptoms had long been present, and had been for the most part referred to uterine disorders. Irritability of the bladder is so common an accompaniment of uterine disease that it is easy to understand how both patient and doctor may be deceived by the symptoms produced by stone; but I would warn you, in all cases of uterine complaint, not to be satisfied without making both a rectal and a vesical examination if the symptoms are at all obscure or do not yield readily to appropriate treatment. When a vaginal examination is being made, it is so easy to pass the finger into the rectum and to slip the uterine sound (if no more convenient instrument is at hand) into the bladder, that there really is little excuse for overlooking disorders of any of the pelvic viscera.

The treatment of stone in the bladder of the female has been simplified almost as much as that of calculus in the male by the "one-sitting" method of lithotripsy introduced by Bigelow. In former years I should have hesitated to break up a stone weighing an ounce and have probably had recourse to vaginal lithotomy, of which I shall speak presently. Of course lithotripsy for small stones has been often performed in the female, and I ventured some years ago thus to break up a small mulberry calculus, the fragments of which may be seen to be covered with phosphates. The ordinary lithotrite, or a shorter one made for the purpose, may be readily employed, or where, as in the great majority of cases, the stone is soft and friable, recourse may be had to simple lithotomy forceps and the crushing power of the hands. Bigelow's, Thompson's, or Clover's evacuator may be employed in the female as in the male, but I think I saved time in my case by using simply a vulcanite urethral speculum and washing out the fragments with an ordinary Higginson's syringe.

Extraction of small stones per urethram with polypus forceps or a scoop is readily performed if the urethra is rapidly dilated in the way I have described; but it is never worth while to drag out large calculi at the risk of producing incontinence, when they can be so easily reduced in size by crushing. The method is, however, very satisfactory for the removal of the foreign bodies which occasionally find their way into the female bladder. Various ingenious instruments have been contrived for catching, doubling up, and extracting such articles as hairpins; but I have found practically that with the finger introduced through the urethra there is no difficulty in guiding a pair of polypus forceps, and extracting a hairpin or other similar body without the risk inseparable from a supra-pubic lithotomy, which has been performed in similar cases.

The operation of lithotomy in the female resolves itself into a very simple proceeding—viz., cutting through the vaginal and vesical walls where they are in contact, and is hence called vaginal lithotomy. Let me remind you that the peritoneum does not touch the anterior wall of the vagina, which may therefore be divided quite up to the os uteri without risk to that membrane, whereas the pouch of Douglas lies between the upper part of the posterior vaginal wall and the rectum, and is liable to injury by obstetric instruments, &c. Vaginal lithotomy is no new operation, for it has been long known to surgeons, but the great modern improvement in it is the practice of closing the wound immediately by wire sutures so as to obviate the formation of a vesico-vaginal fistula. I show you three large stones which I removed from different women by this proceeding some years back. The first stone weighs one ounce and a half, and is remarkable, as you may see in the section, for having consisted originally of three angular calculi, which had become fused together in a mass of carbonate and phosphate of lime, measuring 2 inches by 1½, and being 1 inch thick. This I extracted from a woman aged forty-nine, in whose bladder I detected a very distinct pouch, in which no doubt the stone had originally lain. I closed the wound with tin wire sutures introduced through the whole thickness of the bladder and

B B

vagina, and the patient made a perfect recovery. The second stone is nearly circular in shape, its long diameter being 2½ in. and its short diameter 2½ in., and its greatest thickness 1½ in. It weighed two ounces, and I extracted it from a woman aged forty who had long suffered from pain supposed to be uterine. In this case the closure of the wound was not entirely successful, and she had slight incontinence when in the upright position, but declined further interference. The third stone consists of one large mass and a quantity of débris, weighing altogether three ounces and a half, which I extracted from a woman aged fifty, who made a perfect recovery.

You will thus see that there is no difficulty in extracting very large calculi from the female bladder entire, but it is in some sense a reproach to our art that stones should be allowed to attain such a size. Early detection is as desirable in the female as in the male, and the great majority of such cases can be best treated by lithotripsy at one sitting.

## COMPOSITION, RESOLUTION, AND ABEYANCE OF SECONDARY PERCEPTIONS.

By BRIGADE SURGEON T. OUGHTON,  
ARMY MEDICAL DEPARTMENT.

DIRECTIVE phenomena are affected by muscles influencing one another, as well as by the mechanical arrangement of their constituent fibres. Such was a cursory rejoinder to a hypothetical objection to the motor diathesis of the secondary perceptions on the ground of the multiform and incongruous distribution of the fibres of certain muscles—the pectoralis major, penniform muscles, &c.<sup>1</sup> It is a rejoinder meriting critical examination, since the problem of secondary perceptual currents being conducted centripetally from a voluntary muscle during its vital contraction must be incompletely verified, if not quashed, without its due acceptance. Taking it, then, as a text for the present remarks, I trust that abundant evidence will be forthcoming in its support, which will also have a practical bearing on the further proof of the problem in question.

*Composition.*—A very good and simple illustration of this nervous process is afforded by the following observation:—"The left eye may perceive an object eight degrees to the right of the main line of direction, and the right eye four degrees; but binocular vision will give it its correct value of six degrees by virtue of muscular co-operation and the agency of a directive composition."<sup>2</sup> It is an absolute essential for the dynamic composition of secondary sensorial forces that the muscular fibres engaged in the operation be consensual—that is, pull in the same direction more or less. 1. Note the parallelism of the elementary fibres of a voluntary muscle in contrast to their intricate interlacings in an involuntary and non-directive muscle. They would doubtless have been perfectly parallel were it not for the convenience in packing, admirably shown by Paley, arising from thin tendinous sheets and delicate cords. Composition renders perfect parallelism unnecessary, however; the fibres agree in their general direction, and the muscle's contraction generates a single directive resultant. 2. Observe how the numerous muscles of a set (flexors on the forearm) operate sensorially as one muscle would do when unified in one particular action (flexing the hand). Many muscles are indispensable for the attainment of various distinct ends, but muscular consent originates a directive unification where it would be useful. 3. The phenomenon of single vision has been interpreted by a consensual theory; the external rectus of one eye pulls in the same direction as the internal rectus of the other eye, thereby initiating a directive composition. There is a strict analogy between this case and that of a single muscle or set of muscles. Hence an objection to the motor diathesis of the secondary perceptions, on the ground of the extremely irregular form (pectoralis major), or distribution of the elementary fibres (penniform) of certain voluntary muscles is a weak one. Should it be sought what single directive message any muscle (penniform or otherwise) transmits to consciousness, it will be necessary merely to note the relative positions of

its osseous attachments, and the direction towards which the movable segment is turned by its shortening, so that the directive message is determined by the mechanical conditions of a muscle's origin and insertion. But, mark here, nothing will be more natural than to conclude that this result could not obtain excepting the relative positions of osseous origin and insertion are known by a sort of inner consciousness; the superior rectus, for instance, rotates the ocular globe upwards, it may be concluded that the resulting upward idea has no *points d'appui* for its realisation in the absence of a recognition of the sites of origin and insertion of the muscle by a latent process of consciousness. I regard such a conclusion as erroneous, inasmuch as latent or inscrutable consciousness is incomprehensible; the directive message, although due to mechanical conditions, has no further reference to them, referring only to any sentient point or points that may be impressed *ab externo*. Thus, the biceps has a sensorial reference to any impressed sensitive point either on the hand or the forearm, and not to its bony attachments; again, the muscles rotating the body or the head may have a directive reference to an impressed retinal point. From a very simple starting-point we now find ourselves at the complex borderland where the Ego and the Non-ego meet; there is the natural cohesion of the insensate tendinous and bony origins and insertions (the Non-ego) in juxtaposition with and holding relation to an independent agency—namely, the vitalised cohesion of muscular contraction (one main-spring of the Ego). Nothing remains for us apparently but to contemplate these two stupendous forces standing thus face to face; a fair simile of the position is to be found in a pair of horses drawing a tram-car round a corner, the animals being guided as it were by the *vis a tergo* of the heavy tram with its mechanical adjustments.

*Resolution.*—It is an almost axiomatic observation, where one finds composition there one may search for resolution; and it would seem that the latter process is in operation to produce the visible directions of the peripheral portions of the retina. Before entertaining this subject, however, let us consider the direct proofs that visible direction is a motor physiology in the following condensed argument:—

1st. Peripheral retinal points are equally sensitive with the axial point, noticeable in the observation of minute stars; therefore, on the theory that the special nerve of sight is a directive agency, the centre of visible direction will correspond with the centre of the retinal concavity (ocular centre). Sir David Brewster has promulgated this view.

2nd. Prof. Volkmann and Dr. Griffin have shown, each by an independent investigation, that the centre of visible direction is situated at a point considerably anterior to the centre of the retinal concavity; therefore visible direction is not effected by the retina.

3rd. Every object before the single eye, whether median or lateral, is seen accurately in position; therefore the centre of visible direction coincides with the eye's optical centre. The latter is at a point in the crystalline lens near its posterior border—that is, anterior to the centre of the retinal concavity.

4th. Every object appears to be fixed during the rolling of the eyeball (Brewster); therefore the optical centre and the centre of visible direction both coincide with the centre of rotation of the eyeball. Hence (*nisi prius*) visible direction results from the motions of the eye—i.e., its muscular apparatus.

Reference being now made to the following figure, *c* being the optical centre, the straight line, *m m*, will represent the median and main line of monocular visible direction. This line is regarded as being originated by the recti pulling the eyeball evenly backwards by their normal tonicity. Muscular tonicity, according to this view, is a directive agent as well as volitional contraction, and the opinion is corroborated by the directive phenomena resulting from the erect position of the body and the head, both postures being referable to tonicity. The balance of the recti is destroyed when the eye is directed laterally. If the eyeball be turned towards the right, the rectus so rotating it is in a more active state of tension than its fellows, and consequently the axial point, *m*, will now perceive the image depicted on it along a line of direction inclining to the right. But the lateral points *a*, *b*, *z*, or *y* are each equally affected by the greater tension of a given rectus, as is point *m*. How is it that the images impressing these points are not perceived along a line of direction that is parallel to, or identical with,

<sup>1</sup> Vide THE LANCET, July 29th, 1882.

<sup>2</sup> Ibid., October 22nd, 1881.

t of the image on point  $m$ ? Herein consists the paractical problem of visible direction. I hold that the main section,  $mC$ , is resolved into the oblique visible directions  $bC$ ,  $zC$ ,  $yC$ , &c.

Such resolution appears to be warranted when we consider the instability of peripheral retinal points as compared with the stability of the axial point, and that said instability is progressively greater in the direct ratio of the distance of any peripheral point from the axis. Assuming the eye to be looking forwards, it will be manifest that the backward pull of the entire recti operating on the axial point,  $m$ , would draw the eyeball backwards, whilst if operating on

any oblique point,  $a$  or  $z$ , it would tend to rotate the eyeball. Again, the mobility of this rotatory influence will be greater if exerted on point  $b$  than on point  $a$ , on point  $c$  than on point  $b$ , and so on. Further, the tendency of the muscular action to pull the eyeball backwards will be inversely as the tendency towards its rotation; hence the forward direction,  $mC$ , originating with the backward pull, will be modified accordingly. A visible direction corresponding to any oblique point,  $a$  or  $z$ , will not originate such a forward idea as the point  $m$ —that is, it will be inclined to right or left in addition to forwards; neither will a visible direction corresponding to points  $b$  or  $y$  originate such a forward idea as the less oblique points  $a$  or  $z$ —that is, it will be more inclined towards the right or left. Thus the causation of the progressive scattering of visible directions from retinal centre in circumference, as with other directions, is determined by mechanical condition (the globular shape of the eyeball). The backward pull (the forward idea) will be very slight at the peripheral points  $c$  and  $x$ , but it is still there; in other words, the main direction,  $mC$ , is resolved into the dotted lines indicated in the diagram.

In what manner the site of the centre of visible direction is fixed at point  $C$ , correspondent with the eye's centre of motion, is a less abstruse inquiry. That the progressive scattering of visible directions must cause them to intersect at a common point eventually, will be evident on considering that the directions are different on either side of the median line  $mC$ , and that the eyeball is globular. Why, then, at point  $C$ , or how are the visual angles  $mCa$ ,  $acb$ , &c., generated? Confining our attention to the images  $m$  and  $a$  of the objective entities,  $M$  and  $A$  with visual angle  $mCa$ :—(1) Retinal points are impressed by light for one-eighth of a second. (2) The glances of the eye must be considerably more rapid than this, since even the movements of the hand are more rapid; an ignited piece of charcoal revolved in the hand deceives the retina by producing the semblance of a fiery circle. (3) Therefore, in directing the eye rapidly from object  $M$  to object  $A$ , the retinal points  $m$  and  $a$  will be impressed by the images of these objects simultaneously for a definite period. (4) Therefore the visual angle  $mCa$  will be identified by perception, and this angle will be formed at point  $C$ , the eye's centre of motion. (5) Therefore every single visible direction into which the main visible direction is resolved will have a fixed value for a certain retinal point; thus,  $aC$  for the lateral point  $a$ . Let it be understood that muscular traction reacting on the mechanical sphericity of the retina generates visible resolution, whilst ocular rotation affects monocular visible direction.

Other phenomena that are probably determined by directive resolution may be briefly alluded to: I refer to the visible area correspondent to the punctum cæcum, and to the resolution of main tactile directions correspondent to the manifold sentient points on the skin's surface. The latter forms a fit subject for reflection and analytical investigation.

*Abyeance.*—There are two varieties of this process—viz., the subordinate and the insubordinate. The directive and positional perceptions of the sense of touch are subordinated to those of vision, as indicated in the following original experiment: Holding the thumb and forefinger midway between and a few inches before the eyes, let them be rubbed together. Looking now with both eyes at a remote and median position, two spectral thumbs and forefingers will be seen, and with these singular results: When the optical axes (still divergent) are inclined to the right side, the forefinger will feel the thumb at the site of the right spectrum; on inclining the axes leftwards, the thumb will be localised on the left side. The same tactile abyeance may be proved by studying one's face in a distorting mirror; however much the forehead is seen to recede abnormally, its parts will be accurately felt by the fingers just wheresoever they may be seen. Brewster's well-known experiment with the cane-chair,<sup>3</sup> in which the octagonal perforations of the seat are felt in a different position to which they are seen, does not invalidate the above statement; this is apparently an example of single vision, but really one of double vision with a sensorial antagonism operating between the ocular muscles. Is it possible that a tactile positional perception can be in abyeance to visual positional perceptions that are at variance so as to neutralise each other? Certainly not; in such an event, as a result of the first experiment, the thumb would be felt by the forefinger at the sites of both the visible spectra simultaneously.

Another example may be instanced in viewing objects behind by bending the body forwards and looking between the legs; the superior rectus now localises objects below and the inferior rectus above, because these muscles are in abyeance to those bending the trunk. Muscular abyeance exhibits many manifestations in the upper extremity, concerning which it may be said generally that a given distal segment is subordinated to any given proximal segment—the fingers to the hand, the fingers or hand to the forearm, and this to movements of the arm. The index finger indicates direction or position only through the abyeance of the indicator muscle to wrist, elbow, or shoulder movements, which clearly modify its indications. Analogously taking a natural skeleton of the upper extremity, the phalanges may be moved independently of the metacarpal bones, but not *vice versa*; and the carpus may be moved independently of the humerus, but not *vice versa*. Hence a practical illustration is afforded of a statement made elsewhere that "the muscular organism of the secondary perceptions is correlated to the mechanical forces of nature in like manner as that of the primary perceptions is correlated to the sense essences of nature";<sup>4</sup> other facts endorsing the same doctrine are contained in the present thesis.

A single instance of insubordinate muscular abyeance must suffice—namely, it is the usual province of the right external rectus to give rise to a rightward perception; but, rotating the face over the right shoulder, the resultant perception of this muscle is a backward one. In this experiment the rectus is not in abyeance to the rotatory muscles of head, but it co-operates with them, whilst remaining *per se* an efficient factor throughout. The result is due to an absence of inconsistency or antagonism between rightward and backward directive perceptions. A mechanical equivalent of the process is afforded by two rulers that are fixed end to end at right angles, and that rotate on the free extremity of one of the rulers as on a centre.

Derby-villas, Forest-hill, S.E.

<sup>3</sup> Brewster on the Stereoscope, p. 95, 1856.

<sup>4</sup> Vide THE LANCET, July 29th, 1882.

THE Visiting Committee of the Holborn Infirmary at Highgate have reported that, in order to meet the demand for admission at the present time, they have made arrangements to provide fifty-two additional beds, and instructed the clerk to write to the district medical officers, calling attention to the crowded state of the infirmary and asking them to treat cases as far as practicable in their own districts, and send only urgent cases to the infirmary.

ON THE  
SAFE ADMINISTRATION OF CHLOROFORM.

By WM. MARTIN COATES, F.R.C.S.,  
SURGEON TO THE SALISBURY INFIRMARY, FORMERLY TEACHER OF  
ANATOMY AND MIDWIFERY IN THE ÉCOLE PRATIQUE DE  
MÉDECINE, PARIS.

In the year 1858 I made known to the profession in a *brochure* my views on the "Safe Administration of Chloroform." This little work was most favourably reviewed by the medical press, and several surgeons more or less eminent wrote to me their conviction that I had solved the problem of greatly limiting, if not abolishing, the dangers of this anæsthetic. By experiments on frogs and observations on patients, I had become convinced that chloroform could only be safely administered by limiting the dose to the smallest quantity capable of inducing insensibility to pain. By repeated trials I found that by means of Snow's inhaler five minims of this anæsthetic, followed by ten in twenty seconds, and in forty seconds by fifteen, and then fifteen every minute until the patient became insensible, and afterwards an occasional ten minims, sufficed in almost every case to produce and maintain complete anæsthesia. Very rarely twenty minims were required. It was found that when fifteen minims were put into the inhaler every minute during the inhalation all the chloroform had evaporated at the end of that time. I have reason to think that from the publication of these facts the doses were much moderated, and that in consequence the number of deaths became relatively less. Although I have during these twenty-four years never been prevented administering it by extreme age or infancy, by chronically diseased heart, lungs, or kidneys, I have not had a death by chloroform. Considering that I have been surgeon to the Salisbury Infirmary during all these years, and have had during that period a numerous *clientèle*, this evidence will not, I trust, be considered unimportant. I have read with painful interest the reports of deaths from chloroform, and have not come across one in which this mode of giving it had been adopted. In every case of death in which the quantity of the anæsthetic inhaled was recorded, it was much larger than that advocated by me. Of late years a quicker and more daring plan has been advised and practised. Hence, I feel sure, the more frequent fatal results. During these twenty-four years I have never refused chloroform to any patient in whose case pain was anticipated. The scares inducing pressure of the chest, placing the head below the level of the body, &c., have not occurred. Sometimes those who have kindly administered the chloroform have preferred the towel and handkerchief. This I consider dangerous, and now always request that the plan detailed above be adopted. By it the sickness, headache, and malaise, following operations performed under chloroform, are immensely diminished. Some timid patients fancy that the mouthpiece of the apparatus will suffocate them. In such cases I sprinkle ten minims of the anæsthetic on a handkerchief, and when it begins to act return to the inhaler. Mr. Matthews has supplied me with three sizes of mouthpieces, surrounded by inflated indiarubber tubes and more perfect valves. These are much better than those used by Dr. Snow. When the towel or handkerchief is used the dose must be more than doubled, as more than half is lost by evaporation and expiration; but then the atmosphere becomes loaded with vapour, and if danger should arise the chances of life to the patient would be much diminished. It would seem almost unnecessary to give facts or arguments to prove my position, for what would any educated practitioner think of one who having made up his mind to give a grain of opium every hour for twelve hours gave twelve grains at once? or having decided to give twenty grains of chloral every four hours for twelve hours administered sixty grains at one dose?

I admit that these are extreme illustrations, but the principle is the same. We all know that some patients are prone to be rapidly and profoundly affected by mercury, opium, and chloral hydrate, &c. I am certain that some, and not a few, are dangerously affected by the usual doses of chloroform. Curiously, I have had several illustrations of this in the wards of the Salisbury Infirmary lately. One young woman of twenty-four years of age was completely

narcotised by five minims of chloroform. A middle-aged woman was rendered insensible to pain during an operation lasting a quarter of an hour by seventy-five minims, and a child by ten minims. Had the usual doses been given to these patients, would not their lives have been placed in danger? I think so. I admit that in most cases by the withdrawal of the anæsthetic, opening the windows (which during the inhalation should never be shut), &c., the patient is mostly saved, and the fatal cases reduced to one in a few thousands, but to that one this makes all the difference between life and death.

It has been said above that I have not in one instance refused to give chloroform because of diseased heart, feeling that indications of danger would declare themselves in time to combat them. Two illustrative cases have occurred in private practice during the last few weeks. One was a gentleman seventy-nine years of age, on whom I performed colotomy. His pulse was very feeble and intermittent. The other case was an elderly lady with tricuspid insufficiency very marked. These cases have an additional interest from my having made an important addition to my usual method of giving the anæsthetic. It struck me that it might be useful in the cases in which the heart showed symptoms of powerlessness to give a dose of pure ether by inhalation in the same relatively small quantities with the view of rallying this organ. These two cases prove, I think, that this idea is a valuable one. The old gentleman was given chloroform after my method, and when the pulse dropped at all twenty minims of ether were put into the modified Snow's inhaler. The pulse on each occasion answered to the whip instantly, and was firmer and more regular at the end of the operation than at its beginning. The elderly lady suffered from hæmorrhoids at both sides of the anus, and from a very painful fissure. She was very anæmic, and her skin was of the colour so familiar to us in cases of malignant disease. We could, however, detect none. A gentleman who had had much experience in giving chloroform with a towel or handkerchief, declined, in consequence of the tricuspid disease and extreme anæmia, to be the administrator. As this case was more than usually risky, I requested Mr. Harcourt Coates to operate, I administering the anæsthetic. The patient objected to the inhaler. Ten minims of chloroform were dropped on a handkerchief which was placed over her mouth and nose. She soon became sufficiently unconscious to admit of the use of the inhaler. The operation lasted from first to last half an hour. She was kept insensible to the pain by seventy-five minims of chloroform and the same quantity of ether. Her pulse varied but little during the half hour. When it became a little depressed, twenty minims of ether raised it instantly. In no case since the year 1858 have I had to use galvanism, nitrite of amyl, artificial respiration, or any other mode of resuscitation.

My readers have, no doubt, compared the small doses of ether with those habitually given. May it not be that the same freedom from danger from this anæsthetic would be attained if the necessary quantity only was inhaled? Before I publish my contemplated next edition of the little work on "Chloroform and its Safe Administration," I hope to work out this practically, both as regards ether and the bichloride of methylene. The economy of chloroform is necessarily very great by this method. I admit this to be of least consequence. Am I rash in concluding that the foregoing facts are calculated to prove:—

1st. That the plan advocated is rational and consistent with our practice with other powerful remedial agents.

2nd. That it lessens the dangers and after disagreeable effects of the anæsthetic, and so would enlarge the area of its utility?

If so, I am very thankful; as the frequent deaths lately reported, should they continue to occur, would naturally increase the anxieties both of the public and of ourselves, and might limit to a fearful degree the blessing of that merciful gift of God, anæsthesia.

Salisbury.

THE practice of tobacco smoking appears to be largely on the increase in the United States. Among youths especially it is rapidly extending. The head master of the Latin School at Boston, Mass., states that tobacco is used by half the boys in the upper classes in his establishment, while the principal of Harvard Grammar School in Charlestown avers that out of 300 boys about 40 per cent. use tobacco habitually.

# CASES SUGGESTIVE OF A PROBABLY PROLONGED INFECTIOUSNESS IN SOME CONVALESCENTS FROM SCARLET FEVER.<sup>1</sup>

F. SPOTTISWOODE CAMERON, M.D., B.Sc. EDIN.,  
ON. PHYSICIAN TO THE HUDDERSFIELD INFIRMARY; MEDICAL  
OFFICER OF HEALTH AND PHYSICIAN TO THE BOROUGH  
FEVER HOSPITAL, HUDDERSFIELD.

THE question how long the poison of scarlet fever may  
remain about the person of a patient, convalescent from the  
disease, is at once so important and so difficult to answer,  
I shall perhaps be pardoned, as the following cases are  
somewhat suggestive, for giving such particulars of them as  
either come under my own observation, been furnished  
for the purpose by my friend Dr. Stewart, or gathered  
from the relatives of the patient.

On Tuesday, Feb. 14th of the present year, Ada, the eldest  
child at home of George B—, a journeyman mason, was  
sick with vomiting, and complained of a sore-throat. On  
Wednesday the skin of the chest was covered with "small  
red dots," the face was flushed, and the child was feverish.  
The mother attached no great importance to the symptoms,  
the child was delicate and often ailing. She kept her  
nurse, in bed, but next day (Thursday) during her mother's  
absence, the girl got out of bed and went to the outer door.  
It would appear to have thus got a chill, for the reddening  
rash on the skin disappeared, and on the following Monday  
the mother noticed a slight swelling or puffiness of the face.  
There was also swelling of the hands and ankles, and these  
symptoms so alarmed the girl's mother that next day she  
called Dr. Stewart to see the child. This he did on Tuesday,  
Feb. 21st. Feeling in some doubt as to whether the child  
might not have had a slight attack of scarlet fever, Dr.  
Stewart advised that the two other children should be sent  
away. They were accordingly sent to Mrs. B—'s mother,  
at the door, and remained there, as we shall see, some eight  
days. I am informed that there was no intercommunica-  
tion between the houses, but I do not ask anyone to accept  
this literally. The arrangement, however, was probably as  
efficient, or as inefficient, as the separation of a scarlet fever  
patient in one room of a moderate-sized house generally is.  
The patient was under medical care till March 13th, and  
as, her mother says, in bed about a fortnight of that time,  
the loose skin peeled off for some time longer. Later, I  
do not learn exactly when, but not till risk of infection was  
supposed to be over, the house was cleaned down, white-  
washed, the paint and furniture washed, the mother's and  
children's dresses and underclothes, the bedclothes, bed-  
ding, even the flocks of the bed itself, washed, while  
mats, old blankets, and some other things of little value,  
which could not be washed, were burned. The mother's  
mats had never been out of their box, and that, for want  
of room, had been all the time at the grandmother's. I do  
not find that Mr. B—'s clothes were subjected to any  
process of disinfection. Otherwise disinfection was carried  
out as completely as, perhaps even more thoroughly than, is  
usually done by people of the same class, and on March 23rd,  
over more than five weeks from the date of attack, the  
mother, mother, and convalescent moved to another cottage  
out a quarter of a mile distant. Rather more than three  
weeks after, when they had got thoroughly established, the  
two younger children were brought to the new home. This  
happened on Sunday, April 16th, nearly nine weeks from  
the commencement of the patient's illness.  
The second girl, Florence, a child of four, slept with Ada  
at night, and next (Monday) morning was sick, vomited,  
and complained of sore-throat. On Tuesday she had a rash,  
more distinctly marked than ever Ada had, and Mr. B—'s  
mother, who came in, suspected scarlet fever, and advised  
them to get the doctor. Dr. Stewart's assistant saw the  
child on the 20th; he saw her himself on the 21st, and in-  
formed me of the case on the 22nd, requesting that, as the  
other was expecting to be confined, I would take steps in  
this matter. I saw the children at once, and felt inclined to  
tell both cases scarlet fever. There was a certain amount  
of roughness of the skin still about Ada, hardly typical  
squamation. The younger child had a slightly dusky ring

round the isthmus of the fauces, but no very distinct rash.  
I explained to the father the state of the case—that I could  
not say more than that probably both children had had  
scarlet fever, and offered, if he was willing to run the risk,  
to send them to the scarlet fever ward at the borough hos-  
pital, but gave him the alternative of sending them both to  
some friend who had no children, and who did not intend to  
be with his wife during her confinement. I gave him an hour  
to make up his mind, and he elected to send the children to  
his wife's sister, a married woman without family. They  
were sent to Mrs. R—'s, about half a mile away, at once,  
and the house emptied of people and well stoved with brim-  
stone by one of our inspectors. Mrs. B— had a slight  
sore-throat at the time the children were sent away. That  
night Mrs. R— took the second child, Florence, into her  
own bed, and next morning (Sunday, April 23rd) she was  
sick, had a sore-throat, and the following day a red rash.  
When I saw her, a few days later, she was suffering from a  
well-marked attack of scarlet fever. The children remained  
there till after their mother was confined, and till after Mrs.  
R— herself had quite recovered. Mrs. B— was confined  
on May 23rd, and did well.

When Dr. Stewart considered the cases ready for dis-  
infection, the corporation officials fumigated Mrs. R—'s  
house, removed for disinfection the bedding, bedclothes, and  
clothes, and some eleven weeks from the time they had been  
sent away the children returned home. A few days later  
the third child, a boy of twenty months, was attacked in a  
similar way. His mother brought him, as an out-patient,  
to my clinical at the infirmary on October 31st. He has  
never been thoroughly strong since his illness in the summer,  
and has a trace of albumen in his urine.

The points of special interest about these cases are—  
(1) That a child, nearly nine weeks after the commencement  
of her own illness, should apparently have conveyed the  
poison of scarlet fever to her sister by contact; and (2) that  
an ailment so little marked, that one hesitated to incur the  
risk of sending the children to the fever hospital, should  
apparently have been infectious enough to cause a well-  
marked attack of scarlet fever in a healthy adult, who, as  
we learned afterwards, had not previously had the disease.

The amount of scarlet fever in the borough at the time  
was below the average of the same season during the three  
previous years. From the middle of April, for six weeks,  
it was as nearly absent as this disease ever is from a large  
town.

My own feeling about the infectiousness of scarlet fever at  
present is, that it is unwise to allow children to mix with  
others till desquamation has quite ceased, and my expe-  
rience, during the last few years, of close upon a thousand  
cases of this disease at the borough hospital, is that the  
process is seldom completed before the eighth week, is often  
incomplete at the tenth, eleventh, and even the twelfth week,  
and is by no means always ended at the thirteenth week.

Huddersfield.

## CASES OF STRANGULATED HERNIA, AND THE TREATMENT OF OMENTAL PROTRUSIONS.

BY JOHN TUDOR, M.R.C.S.,

SENIOR SURGEON TO THE DORSET COUNTY HOSPITAL.

CASE 1. — H. W—, railway porter, aged twenty-eight,  
was admitted into the Dorset County Hospital on Oct. 13th,  
1864, with a large hernial protrusion in the right inguinal  
region of some years' standing, for which he had been in the  
habit of wearing a truss. Two days previous to admission  
the truss was left off. The man having been drinking rather  
freely, and being unable to return the hernia, which hitherto  
he had been able to do without trouble, he was obliged to  
send for a surgeon, who was also unsuccessful in returning  
it. At the expiration of two days from this the patient was  
sent to the hospital. He was at once put under the influence  
of chloroform, but no impression could be made upon the  
protrusion, which was very tense and painful; and as the  
man's condition was becoming critical, I without delay cut  
down upon it. The sac was opened, and found to contain  
an extensive mass of highly coloured omentum, also a large

<sup>1</sup> A paper read before the Huddersfield Medical Society, Nov. 7th, 1882.

coil of intestine of a bright-red tinge. The stricture at the internal ring was divided and the gut returned; a strong double hempen ligature was passed through the centre of the omentum just in front of the internal ring, and firmly tied upon either side, which was then cut off about a quarter of an inch in front of the ligatures, the ends of which were allowed to hang out of the wound, thus keeping the stump *in situ* and maintaining a free drainage. The omentum removed weighed a little over a quarter of a pound. The subsequent treatment consisted in giving opium freely and covering the abdomen with hot fomentations. A simple fluid diet was maintained for the first few days, until there had been a free action of the bowels. On Oct. 31st, three weeks after the operation, the notes record: "The patient has progressed well without a bad symptom." I heard of this man sixteen years afterwards, and the report stated that he was very well.

CASE 2.—J. G., aged sixty-five, a spare, healthy man, the subject of crural hernia for some years, was admitted into the Dorset County Hospital on April 23rd, 1867. The gut had been strangulated for four days, accompanied by continuous stercoraceous vomiting. The protrusion had passed upwards over Poupart's ligament, and had been mistaken for an inguinal hernia, and sedulous attempts had been made to reduce it as such. Aperients had been freely given by the mouth, and also by injections. The most troublesome symptom upon admission was the constant fecal vomiting. There was but slight pain and little swelling of the abdomen. Under the influence of chloroform, a cautious attempt was made to return the gut, but without success. I then decided to operate. Upon opening the sac, dark-coloured serum escaped. The hernia consisted of omentum and gut, the latter being of a dark mulberry colour, and adherent to the omentum, which was also adherent to the sac. The adhesions were very firm, and required great care in separating them. Gimbernat's ligament was divided, and the bowel returned. The omentum was ligatured and divided by scissors. The after-treatment was essentially the same as that carried out in the former case, and the patient did well. Some years afterwards I had the opportunity of examining the man, who was "radically cured," and could do his work without the use of a truss. I again heard of him at the age of eighty, when he was enjoying good health.

CASE 3.—I was summoned, late in the evening, April 21st, 1881, to see an old lady, aged fifty-eight, living in a town about eighteen miles distant, suffering from strangulated crural hernia. I found her rolling about in her bed in great agony, proceeding from a hernial protrusion in the right groin about the size of a cricket-ball. She had been the subject of hernia for about twenty years, which had never been returned. The usual size of the protrusion had been about that of a hen's egg. Upon the day of my being called in the patient over-exerted herself, and the tumour rapidly increased in bulk, accompanied with great pain. She was at once put under chloroform, and, after a careful attempt at reduction, I operated. Upon opening the sac, it was found to contain a large mass of omentum and a considerable-sized knuckle of intestine. From the large bulk of the two together, great care was required in dividing the stricture. The omentum was raised up and held over the side of the abdomen, whilst the gut was shielded by an assistant, and the stricture was carefully divided upon the fingers. The gut being returned, the omentum was ligatured and excised. It was quite a handful, and weighed over two ounces. In this case the ligatures were much longer in coming away than usual—the one not until after four, and the other three, weeks. Morphia and extract of belladonna were given at intervals. At the end of three days oil and turpentine injections were administered, but without effect. At the expiration of a week I was telegraphed for, as the patient was thought to be dying. There had been no action of the bowels, in spite of the treatment, and the patient was in great distress. The abdomen was very much swollen and tympanitic, and somewhat painful to the touch. I concluded it was a case of extreme flatulent distension, with muscular inertia, but with an absence of inflammatory complication. I advised an enema containing two ounces each of castor oil and spirits of turpentine, with one drachm of tincture of opium, to be carefully blended with the yolks of two eggs, and to be administered in two quarts of thin gruel as warm as could be borne. This had the immediate effect of bringing away a large volume of flatus and small quantities of feculent matter, which gave instant relief and reduced the abdomen to its normal dimensions. Six grains

of calomel were placed upon the tongue, and a senna draught ordered for the morning. During the night there were two copious motions, and from this time the patient made a favourable recovery.

CASE 4.—On September 11th, 1881, I was telegraphed for into the country to see a gentleman, aged about seventy, suffering from strangulated femoral hernia. The patient had been the subject of rupture for some years, for which he had consulted a well-known London surgeon, who pronounced it to be omental. Having failed to return it, he advised the use of a truss. This was several years ago. Six days before I was called in the patient felt unwell, accompanied by sickness, and followed by constipation, for which he was ordered effervescing medicines and aperients, which failed to give relief. Upon my arrival I found him very feeble and low-spirited, having been unable to take food for some days, fluids even being rejected. The countenance was haggard and anxious, the pulse quiet and compressible, tongue dry and furred, and the vomit stercoraceous. The abdomen was painful and tympanitic, and there was increased tenderness over the seat of hernia. The case seemed in all respects critical, for in addition to the above symptoms, the age of the patient, the duration of the illness, with a weak heart's action, were to be taken into consideration. I advised immediate operation as the only chance. The patient was placed under chloroform, and I cut down upon the hernia, opening the sac. There were slight adhesions between the gut and omentum, and between the latter and the sac. The gut was of a dark-purple colour, and the stricture unusually tight at Gimbernat's ligament. The omentum, which was of a dark-red colour, was ligatured and cut away with scissors. The patient was ordered ice to suck, and to take small doses of opium and belladonna, whilst the abdomen was covered with hot fomentations. This gentleman, under the careful management of his own medical man, subsequently made a very favourable recovery.

CASE 5.—On March 16th, 1881, I was telegraphed for from a town some distance away to a Mrs. —, aged fifty-nine, suffering from strangulated crural hernia. There were two protrusions, one in either groin, about the size of a walnut; that on the left having existed for seventeen years, and that on the right for ten, neither of which had ever been reduced, although, the patient stated, that she had worn a truss upon the left side for ten years. Four days previously to my being called in she complained of pain in the right groin, which was soon followed by vomiting and other symptoms of intestinal obstruction. The vomit shortly became stercoraceous, and continued so for three days, up to the date of my visit. Upon examination there was but slight swelling over the abdomen, and the chief pain was referred to the right groin. Under these circumstances I determined to operate upon this side if reduction under chloroform failed. This being the case, I cut down upon the protrusion, opening the sac, which contained a small piece of ileum about the size of the first two joints of the little finger, which was of a dark-purple colour. There was very little fluid; but the gut was so closely enveloped by the sac as to render it necessary to be very cautious in using the knife. The patient was ordered ice *ad lib.* to suck, and a pill composed of half a grain of morphia and a quarter of a grain of extract of belladonna every six hours. She made a good recovery at the end of three weeks. During the time the patient was confined to her bed the protrusion on the left side disappeared spontaneously.

*Observations.*—It must be admitted that, in the operation for strangulated hernia complicated with an omental protrusion, an important question arises as to how this can be best treated so as to place the patient in the most favourable condition for recovery. The treatment of these protrusions has been clearly and precisely indicated by many able writers, and perhaps the different modes suggested have answered well in the hands of those surgeons who have practised them. I myself have followed one line of practice under the impression that it has superior advantages over the others; and although a few cases might not appear of much value in establishing a principle of treatment, still it seems to me that there are circumstances surrounding the history of those recorded which give a favourable complexion to the proceedings adopted, and taken together, I think they might be considered rather above the average in severity, sufficiently so to test the merits of any treatment and to encourage a repetition of it. The plan of passing a

ature around the omentum and allowing it to slough away has been long abandoned. The different methods now followed seem to be to return the omentum with the intestine, or excise it. Two ways are suggested for carrying the latter effect:—First, by severing the mass, and tying the feeding vessels; and, secondly, by passing a double ligature round what might be called the neck of the protrusion, and securing it on either side; then excising, either by knife or scissors, the mass in front, allowing the ends of the ligatures hang out of the wound to the extent of several inches. As regards returning the omentum into the abdomen, I could always fear the risk of injury to so delicate a structure, however carefully manipulated. And where the protruded part is large, or where it has been down for a length of time, it would appear almost impossible to avoid rupture or tearing, and hence probably establishing a centre of inflammation, leading to peritonitis and its serious consequences. In excising without first ligaturing the omentum I conceive that several risks might be incurred, the most prominent being the retraction of a portion of the cut surface within the abdominal cavity, where oozing of blood or serum might take place, and perhaps giving rise to an internal hæmorrhage or septic changes, probably exciting local or general peritonitis. I can likewise conceive some difficulty in securing small vessels in such a structure. On the other hand, by ligaturing before excising, any risks, it seems to me, might be avoided, and certainly in some instances, as I have related, a "radical cure" might be induced. As I have never followed another plan than that which I have advocated, I cannot profess a personal experience in other methods; therefore I do not attempt to compare any different modes of proceeding which might have been carried out with equal success by other surgeons. But different opinions decidedly exist on the subject, based somewhat upon theory, I bring my views before the profession as the result of practical experience, and after a careful consideration for some years past of a point of treatment which seems essential in importance.

Dorchester.

## POSITION AS AN AID TO THE REDUCTION OF IRREDUCIBLE HERNIÆ.

By BUXTON SHILLITOE, F.R.C.S.,  
SURGEON TO THE LOCK HOSPITAL.

THE following case is, I think, of sufficient interest to justify its record.

I was consulted in June last by a rather stout active lady, aged forty-eight years, mother of ten children, for an irreducible left femoral hernia. The hernia had existed for three years. No truss had been worn and no special notice taken of it. For the first year it frequently went back, but for at least eighteen months it had never returned. Recently it had given rise to some pain without any apparent increase in size. On examination I found a very tense roundish swelling, about the size of a large walnut, in the ordinary situation of a femoral hernia. Neither coughing nor change of position appeared to make any alteration in its bulk. I endeavoured for a considerable time to reduce it, but without making the smallest impression upon it, and I then sent her home, ordering her to keep perfectly recumbent, to live on low spare diet, and to take repeated doses of a saline purgative. I saw her three days after. She had kept entirely in bed, and had followed my instructions. I again attempted reduction, but without success, and I ordered the same treatment to be continued for another four days, when I again visited her, and again unsuccessfully applied the taxis; it appeared to me to be absolutely irreducible. I then explained to her that I was desirous of trying the effect of position upon the rupture, and that I wished her to remain with her head downwards some few minutes two or three times a day. She entered fully into the plan and agreed to give it a fair trial. I had a mattress placed on the floor, and I got her to slip off the side of the bed so that she rested on her elbows on the mattress, her sister and nurse, standing on the bed, holding her up by her legs. The first day she could not bear this position for more than two or three minutes twice in the day; the second day she three times remained for five minutes. On the third day I saw her, and finding no change I recommended that she should

support herself sideways on her right shoulder and arm, one attendant supporting her round her waist, another taking the legs, and a third keeping the left side higher than the right, at the same time that with one hand she gently pushed the tumour in an upward direction towards the feet. For the next two days this was tried three times for five minutes at a time. On the third day, on the third trial (which was continued for seven or eight minutes) it yielded, being, as she described it, slowly dragged into its place. A truss was then fitted, and in a few days she was moving about as usual.

## APOMORPHIA IN CASES OF POISONING.

By AMAND ROUTH, M.D., B.S., M.R.C.P. LOND.

THOSE liable to be called to cases of poisoning are always glad to have an agent handy which, not in itself lowering, will produce prompt emesis, especially in those cases where the jaws are rigidly clenched and the stomach pump absent or inadmissible. This agent I am sure we have in apomorphia, an alkaloid which Dr. W. Murrell has brought before the profession. Though a derivative of morphia, it has no narcotic effects in the doses required to cause emesis. Dr. Murrell recommends it to be kept in a solution of 1 in 50 strength, and to be given subcutaneously in doses of from 3½ to 10 minims (½ to 1 grain). Emesis occurs in from two to five minutes, the contents of the stomach being usually voided in one rush without previous nausea, but with violent and visible muscular action of the stomach walls. The following two cases will serve to show its utility.

CASE 1.—I was sent for to see Mrs. S—, who was said to have swallowed a white powder and to be then dead. I found her on the floor, doubled up, jaws and hands clenched, blood and froth at mouth, respiration seemed absent, and pulse barely perceptible. She had not vomited. Though evidently dying, I injected five minims of the above solution into her arm, keeping my hand on the pulse. In two minutes and a half by the watch the stomach evacuated its contents with a rush, whilst the pulse seemed to rally for an instant and then finally ceased. Oxalic acid was proved to have been the poison used, and at the post-mortem about two drachms only of fluid were found in the stomach.

CASE 2.—A lady, a dipsomaniac, had obtained access to the wine-cellar and had swallowed straight off two bottles and a half of brandy. She then put the corks in her pocket, hid the bottles, put on her clothes, and went out for a walk with her footman. She walked quite steadily for 300 yards, when she dropped down insensible, and was carried home in a cab. On arrival, ten minutes after, I found her comatose, not able to be roused, respiration stertorous and infrequent, pupils dilated and insensible, jaws clenched, pulse slow and intermitting, two or three beats in every eight. Her stomach was full of fluid. I injected 3½ drops of the solution, and in exactly three minutes and a half about a pint of alcoholic liquid was expelled, and altogether in about five minutes a quart (measured) of hardly-altered brandy was vomited. The pulse and respiration now improved, the pupils becoming slightly sensible, and I left her for two hours, by which time she could be roused temporarily. After twelve hours' sleep she awoke none the worse.

Apomorphia fails to cause emesis during chloroform narcotism, but no other drug seems to be antagonistic to it, and there is no reason why it should not be used to get rid of even morphia itself. In the dyspnoea of chronic bronchitis, emesis from apomorphia produces temporary relief. If only the certainty, rapidity, and absolute safety of apomorphia were known, it would undoubtedly form part of every practitioner's paraphernalia.

## ST. GEORGE'S HOSPITAL.

SARCOMA OF THE FEMUR; AMPUTATION AT THE HIP-JOINT;  
RECOVERY; NO RETURN OF THE DISEASE; REMARKS.

(Under the care of Mr. PICK.)

THE following case is interesting, not so much on account of the rarity of the disease, as from the fact that amputation of the hip-joint was performed for sarcoma of the lower end of the femur five years and a half ago, and the patient has remained well and free from any symptoms of a return of the disease up to the present time.

Mary Anne P—, aged nineteen, was admitted into Princess ward on Jan. 10th, 1877. Her history was as follows.—Her parents were both alive and healthy. She had three brothers and three sisters, all living and healthy. She stated that she had never been very strong, and had suffered from enlarged glands in the neck when a child. She had had measles in early life, but no other complaint, and had never been troubled with cough. She had been accustomed to live well and work hard. Catamenia had always been regular; no syphilitic history obtainable, and no history of cancer in the family. About four months previous to admission she noticed that the lower part of the right thigh began to swell, more particularly on the outer side. The right knee also swelled. About a month later the thigh and knee began to pain her very much, more especially when pressed upon, and when she moved. The swelling did not interfere with the motions of the knee-joint, and she was able to walk. She does not remember ever having received a blow or injury of any kind. The swelling did not increase rapidly after its first appearance. For some weeks she attended as an out-patient, and was treated with iodide of potassium. At first the treatment appeared to produce some benefit, the swelling got smaller and she gained weight and strength; but for a month previous to her admission the swelling increased rapidly, and she suffered from a dull, aching pain in the part, which was worse at night.

Upon admission she was found to be thin and slightly built, presenting the appearance of a strumous diathesis. There was a large, smooth and nearly uniform swelling situated at the outer side of the lower end of the femur, of the right side, about two inches above the condyle. The swelling was confined to the outer side of the shaft of the bone, on the inner side and at its lower extremity the femur could be felt to be unaffected. The skin was tense and reddened, but freely movable over the tumour, and some enlarged veins could be seen crossing over it. The swelling was hard and somewhat elastic and firmly connected to the bone, from which it could not be moved. Pressure caused pain, but no sensation of crackling or fluctuation could be felt. Now and again she experienced a starting or shooting pain through the limb. Upon placing a stethoscope on the outer and lower part of the swelling an occasional soft, blowing bruit was audible. The bruit was not constant, and could only be heard at one particular part of the tumour. At this spot, upon making firm pressure, an indistinct feeling of pulsation could be perceived. This pulsation and bruit were felt and heard for the first time on the day after admission, though they had been carefully sought for on several previous occasions. The temperature of the affected limb, especially over the swelling, felt considerably raised above that of the sound limb. There was some enlargement of the glands in the right groin, but the same condition also existed on the left side. The knee-joint was unaffected and could be flexed, extended, and rotated with perfect freedom.

A consultation was held, and it was determined to remove the limb. This was proposed to the patient, but she refused to entertain the proposition and left the hospital. She was lost sight of for a time, but again applied for readmission on

March 12th, six or seven weeks from the date of her previous discharge. The alteration in her appearance was now most marked. She had lost flesh considerably and was much emaciated. There was a hectic flush on her cheeks, and her countenance wore an expression of great anxiety. She was unable to sleep on account of pain, and had entirely lost her appetite. The tumour had grown rapidly, especially in an upward direction, so that the upper margin, which was well defined, reached to within six inches of Poupart's ligament. The skin over it was red, shining, and adherent to the surface of the swelling. There was a distinct pulsation and an audible bruit. The glands in the groin were more enlarged. Amputation at the hip-joint was now proposed to the patient, who willingly accepted any proceeding which would relieve her of her intense pain. This operation was accordingly performed on March 15th by the long anterior and short posterior flap.

The subsequent progress of the case requires no comment. Her recovery was much retarded by the formation of bed-sores, the profuse discharge from which at one time threatened her life. Eventually, however, she rallied and left the hospital with a perfectly sound stump. Six months after the operation a patch of dulness about the size of the palm of the hand appeared at the upper part of the right chest, accompanied by tubular breathing in this situation, and it was found that the disease was returning in the lungs. Gradually, however, it disappeared, resonance returned, and the breath sounds again became natural. The exact cause of it was never clearly made out. At the present time (November, 1882), five years and a half since the operation, the patient is perfectly well, and there are no signs of a return of the disease. She has married, and expects shortly to become a mother.

The tumour after removal was found to be of a soft brain-like consistence and of an almost uniform greyish-white colour. Interspersed throughout its structure were numerous patches of extravasated blood. The tissue of the tumour was arranged in lobules, each of which was surrounded by a more or less distinct capsule. The whole of the lower third of the femur was destroyed and its structure replaced by the growth, which had also extended downwards into the knee-joint. The patella and bones of the leg were unaffected. The microscopical appearances were as follows:—A number of thickly interlacing spindle cells, with distinct nuclei, arranged for the most part in closely set parallel bundles. Intermixed with these spindle cells were a number of irregularly, round, nucleated cells, and in some parts the tumour consisted wholly of these. They were grouped in a delicate stroma, were irregular in shape, and contained two or three nuclei. In addition to these, there were found, here and there, large, irregularly round, multi-nucleated cells, not unlike transparent "giant cells."

*Remarks.*—The disease in this case appears to have belonged to the class of central tumours of bone, in contradistinction to the subperiosteal form of growth; and, as Mr. Butlin has pointed out in his Lectures at the College of Surgeons, the "treatment of central sarcoma of the femur is very much more hopeful than of subperiosteal sarcoma. That amputation high up at an early period of the disease may be undertaken with very fair prospect of success, if not of permanent recovery, at least of long relief." This case seems to bear out Mr. Butlin's opinion. Nothing could have been more unpromising at the time of the operation; the rapid growth of the tumour and the considerable emaciation which had taken place during the six weeks or two months immediately preceding it induced us to regard the case as one of a very malignant type, and to give a most unfavourable prognosis. Happily, that opinion has not been verified by the subsequent history of the case.

## NEWCASTLE-ON-TYNE INFIRMARY.

GASTROSTOMY IN A CASE OF MALIGNANT STRICTURE OF THE ŒSOPHAGUS; REMARKS.

(Under the care of Dr. G. H. HUME.)

J. H—, a labourer, aged fifty-seven, was admitted on August 3rd. Twelve months previously he had first found difficulty in swallowing, and had cough and shortness of breath. He had attended at the infirmary as an out-patient from time to time, and had bougies passed, which temporarily relieved the difficulty in swallowing. At the time

his admission he could only swallow liquids. Examination of the chest detected some dulness to the left of the sternum. Articulation, and throughout the lungs a considerable amount of bronchial catarrh. An œsophagus bougie could be passed down to, but not through, a stricture situated nearly opposite the middle of the sternum. For a few days after his admission a considerable amount of liquid food was taken, and, with rest in bed, the patient's condition appeared slightly to improve. But the difficulty in swallowing gradually increased, until very little could be taken by the mouth, and life was maintained almost solely by nutrient enemata. Gastrostomy was therefore determined upon; and on the first stage of the operation was performed on Sept. 2nd. An incision, about three inches in length, was made an inch from the left costal margins, its direction being such as to make it terminate at the extremity of the tenth rib. The structures of the abdominal wall being divided down to the peritoneum, all bleeding was completely stopped, and the peritoneum divided on a director. The wall of the stomach, which was readily found lying below the left lobe of the liver, was taken up between the finger and thumb, and a black thread passed through it for the purpose of holding it forward during the insertion of the sutures. These latter were nine in number, and enclosed a piece of the gastric wall, somewhat larger than a shilling. The sutures were passed into, but not through, the wall, so that they did not enter the stomach cavity; and each was passed through all the structures of the abdominal wall, so as to bring the peritoneal sacral in apposition with the parietal peritoneum. The ends of the incision in the abdominal wall were then brought together.

The operation was performed under carbolic spray. During the first part of the operation ether was unfortunately administered instead of chloroform, and it was probably in part due to this that on the evening of the day of operation the pulmonary catarrh was considerably increased.

Sept. 3rd: Catarrh much increased, though the patient had a good night. Temperature 100° F.; pulse 86. The enemata were continued, and use was also made of Slinger's nutrient suppositories.—5th: Great thirst and hunger complained of; breathing, which has been very bad, is somewhat relieved. Temperature 99°; pulse 82.—6th: On removing the dressings the exposed portion of the stomach wall was found covered with lymph, and firm union seemed to have taken place to the edge of the incision. The stomach was therefore opened with a tenotomy knife, the incision being just large enough to admit easily a No. 10 gum elastic catheter. Some milk was poured into the stomach by means of a funnel and tube attached to the catheter. Feeding with milk and brandy and beef-tea was continued from this time at regular intervals, and the enemata were administered as before.—7th: The patient has had a good night. Temperature 99°; pulse 80.—9th: The difficulty of breathing, which had become less distressing, has again increased, and there is now a dusky appearance of the face. There is slight wandering.—13th: The patient died.

*Post-mortem examination.*—The body was much emaciated; the left lung was consolidated, especially the lower lobe, and gangrenous in parts. Similar gangrenous masses were scattered through the right lung also, but were less numerous. Opposite the fourth dorsal vertebra the œsophagus was found to be constricted by an annular deposit in its wall of a scirrhous nature. This constricting ring was almost an inch in longitudinal depth. The stomach was adherent to the margin of the incision, and there was not the slightest trace of inflammation either on the peritoneum or wall of the stomach.

*Remarks.*—This case was, undoubtedly, in some respects, a favourable one for gastrostomy. The cancerous formation in the wall of the œsophagus was of limited extent, and had not involved surrounding structures. Probably a lengthened period might have elapsed before life was threatened by the invasion of the air-passages and large vessels. It is a matter of regret, therefore, that the operation was not performed earlier, before the patient's strength had become exhausted, and the consequent condition of the lungs developed. The operation in itself does not appear to be attended by special danger. When peritoneal surfaces are placed in accurate contact they speedily unite, so that the general cavity is shut off, and there is little risk of discharge entering it from the wound. The case only serves to illustrate the well-recognised truth that gastrostomy to be of service in prolonging life must be had recourse to in good time.

## Medical Societies.

### OPHTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM.

*The late Mr. Critchett.*—Hydatid Tumour of Orbit.—Panophthalmitis.—Large Ivory Exostosis of Orbit.—Hard Chancre of Inner Canthus.—Central Amblyopia in Diabetes.—Optic Neuritis.—Tortuosity of Retinal Vessels.

THE ordinary meeting of this Society was held on the 14th inst., Mr. W. Bowman, F.R.S., President, in the chair. He alluded in feeling terms to the sad loss they had sustained in the death of Mr. Critchett, in whom they mourned a warm-hearted, true-hearted colleague, and one whose calm and mature judgment, based on long and wide experience, would be missed by many in cases of anxiety and difficulty. In him Mr. Bowman had lost an almost life-long friend, and although it would be more fitting to attempt a particular enumeration of his claims on some future occasion, he could not help recalling the fact that Mr. Critchett had presided in the chair at the close of the last session. He concluded by reading the following resolutions, which had been unanimously passed by the Council: 1. "That the Council of the Ophthalmological Society of the United Kingdom desire to record their sense of the great loss sustained by the Society, as well as by the profession at large, in the death of one of their vice-presidents, George Critchett, whose extended reputation at home and abroad rested on the solid foundation of important services rendered to that department of the medical art to which he was chiefly devoted, and whose kindness of heart and excellent judgment were universally recognised and esteemed." 2. "That a copy of the foregoing resolution be forwarded to the family of Mr. Critchett with an expression of the cordial sympathy of the Council on the part of the Society under their bereavement."

Dr. P. H. MULES showed a Hydatid Cyst removed from the Orbit, the size of a pigeon's egg. The patient was a boy aged six years; the growth was difficult to diagnose, and was treated by free incision and drainage tubes. The cyst was discharged on the seventh day. Before this, however, a condition of choked disc supervened which interfered with the perfect recovery of vision; but six months after the removal of the cyst he could read.—Mr. HUTCHINSON asked if any echinococci were found in the fluid.—Dr. S. MACKENZIE pointed out that the laminated membrane of the cyst sufficed for the diagnosis.—The PRESIDENT asked whether the firm adhesion of the cyst prevented its being wholly removed at once, for it was very desirable to avoid inflammation within the orbit.—Mr. MILLES mentioned a case lately treated at Moorfields Ophthalmic Hospital where the whole cyst was readily removed, and the wound rapidly healed.—Dr. MULES, in reply, said that the cyst was very firmly adherent, and he did not think it prudent to tear it away.

Dr. MULES also gave particulars of a case of Panophthalmitis. Two or three months before the patient had undergone an operation for glaucoma, which had left a cystoid cicatrix. A panophthalmitis, which he attributed to septic absorption through the faulty cicatrix, destroyed the eye within twenty-four hours of the first symptom of purulent infection.—Mr. PRIESTLEY SMITH said that Leber had recently pointed out the dangers of such cystoid cicatrices. He had himself lately seen a case where the eye was rapidly destroyed from septic inoculation, due probably to an old wound of the iris.—Mr. BRUDENELL CARTER mentioned the case of an old lady operated upon for chronic glaucoma of both eyes, in whom suppuration occurred three years later in one eye, the pus escaping at the cicatrix. There was no evidence of inoculation.

Dr. H. A. LEDIARD (Carlisle) read notes of a case of Necrosis and Spontaneous Separation of a large Ivory Exostosis of the left Orbit. He showed the portrait of the patient, and also the exostosis itself. The tumour was stated to have been about the size of a pea at birth, and was situated between the upper eyelid and the eyebrow. It gradually enlarged, and at the age of nine years, induced destruction and rupture of the globe of the eye. The tumour ceased to enlarge at about twenty-five years of age, and, about two years later, the skin, which had hitherto covered it, suddenly gave way. The patient was admitted into the

Carnarvonshire and Anglesey Infirmary, under the care of Mr. Hughes, in 1870. He was then thirty-three years old, a sailor, and in good health. The tumour seemed to arise from the cavity of the left orbit. It was of stony hardness, irregularly pyramidal in shape, nodulated on the surface, and measured 4.5 by 5 inches; the tumour was then movable, and, whilst under observation, gradually became looser; an offensive discharge issued from the base; finally, about a month later, the whole mass became suddenly detached, without any associated pain or hæmorrhage. The tumour was pediculated, and weighed nine ounces. The neck also was much enlarged, the anterior and lateral portions being of stony hardness, the left side being on this account much larger than the right; the girth of the neck was 17.5 inches, and of this a space of ten inches was of stony hardness. In October, 1882, the patient survived, was in good health, and master of a vessel. The vision of the right eye remained good. Dr. Lediard referred to the other similar cases which he had been able to find recorded. Mr. Hilton reports in Guy's Hospital Reports (1836) a very similar case, where the exostosis, which weighed 14.75 ounces, became spontaneously detached. In a case recorded by Mr. Hutchinson in his "Illustrations of Clinical Surgery," and under his care jointly with Mr. Borlase Child in 1859, the exostosis which was of large size, and appeared to spring from the frontal sinus, also became necrosed. Sir James Paget, in his "Surgical Pathology," mentions another case of large ivory exostosis in the orbit, which projected not only forwards, but also backwards into the skull. Dr. Lediard showed a photograph of the skull in this case, which had been sent to him by Professor Humphry of Cambridge. Boyer had referred to spontaneous necrosis of ivory exostosis, and had remarked on the fortunate nature of the process.—Mr. HUTCHINSON said these tumours had slender pedicles, and if dealt with early they might be removed without much risk, necrosis being a late event. In Mr. Borlase Child's case it took an hour to saw through the neck; it should have been broken off at the root. A year later, necrosis having occurred, the tumour readily shelled out, leaving the orbit much dilated.—The PRESIDENT recalled a case where an exostosis as large as a walnut projected from the orbit; it was easily shelled out.—Dr. FITZGERALD referred to a specimen in the Museum of the Royal College of Surgeons at Dublin, much resembling that at Cambridge. In a case under his own care the tumour sprang from the roof of the orbit, but he did not venture to remove it.

Mr. S. SNELL (Sheffield) communicated notes of a case of Hard Chancre of the Inner Canthus, which occurred in a nurse-girl, aged twenty-one, who had under her special charge a syphilitic infant of five months. The chancre was noticed some few weeks as a pimple before the girl came under observation on Aug. 15th, 1882. It then involved the caruncle and adjacent conjunctiva as well as the integument of the commissure and the lids. A point of interest and diagnostic value was the presence of well-marked induration of the pre-auricular and submaxillary glands. Other symptoms were a papular, coppery rash and alopecia, ulcerated throat, and later on mucous tubercles of the vulvæ. The chancre healed with hardly appreciable deformity.—Mr. BRUDENELL CARTER had seen two instances of hard chancre on the eyelids in young subjects; the mode of infection could not be traced.—Dr. FITZGERALD had seen a case in Paris in a young girl, and had attributed it to direct inoculation.—Mr. MCHARDY suggested that inoculation might arise from the popular practice of using the tip of the tongue to remove foreign bodies from the eyes; or the use of moistened blotting-paper for the like object.—Mr. J. E. ADAMS thought inoculation generally occurred from the sore mouths of syphilitic children through kissing; and Mr. VOSE SOLOMON mentioned a case directly traceable to kissing.

Four papers on the subject of Central Amblyopia in Diabetes were read. The first was by Mr. LANG. The second was by Mr. J. B. LAWFORD, who gave an account of a case of Stationary Tobacco-amblyopia in a man subsequently affected by diabetes. The patient was forty-six and had always been a heavy smoker. His sight had begun to fail about seven years ago, and diabetic symptoms supervened about nine months ago; but his sight had not deteriorated, though the diabetes had grown steadily worse. Vision was very defective, and there was a well-marked central scotoma for red. The optic discs were a little pale, but the ophthalmoscope revealed no other morbid state.—

Mr. STANFORD MORTON communicated a case of Double Amblyopia, with well-marked central scotoma for red and green, in a man, aged thirty-four, accustomed to smoke very moderately, and who was suffering from diabetes. The patient was not under care long enough (barely two months) for the result as to sight to be known.—Dr. EDMUNDS and Mr. NETTLESHIP communicated a paper on the same subject. It contained notes of four cases of central amblyopia without ophthalmoscopic changes, in patients suffering from diabetes. 1. A man aged forty, who had suffered from diabetes for several months. He smoked half an ounce of tobacco a day. Failure of sight had been noticed for one month. Vision in each eye  $\frac{1}{200}$ , letters 14 J. (corrected). Under treatment for diabetes, health improved, but not vision. He would not, however, stop smoking. 2. A man, aged thirty-eight, had had diabetes three or four years. He smoked half an ounce of strong tobacco daily. Failure of sight had been noticed for five months. Vision in each eye  $\frac{1}{200}$  and 14 J. He died in the country three months later. 3. A male, aged forty-eight, had been the subject of diabetes during twenty-one months. He had smoked, during the last thirty years, three-quarters of an ounce of tobacco a day. He had experienced failure of sight for five weeks. Vision was  $\frac{1}{200}$  and 8 J. 4. A man, aged fifty-eight, a moderate smoker, complained that his sight had been failing for eighteen months. Vision in each eye  $\frac{1}{200}$  and 16 J. His urine, on examination, was found to contain sugar. Nine cases were referred to by the authors (including published ones) of failure of sight with central scotoma, in the subjects of diabetes without ophthalmoscopic changes. The authors, however, suggested that the coincidence would prove to be fairly common. Most of the patients were smokers, some of them great smokers; and it was not yet certain whether diabetes alone caused the disease, or only acted as a predisposing cause to tobacco-amblyopia. The analogy of double amblyopia to the symmetrical neuralgia in diabetes, described by Worms and Buzzard, was pointed out.—Dr. S. MACKENZIE pointed out that these cases had all come under the care of surgeons rather than physicians. He had seen two cases, one in a woman. Tobacco was an important factor in their production.—Mr. PRIESTLEY SMITH, speaking of the pathology of central amblyopia apart from constitutional or toxic causes, stated that Samelshon of Cologne had suggested that inflammation of the central parts of the nerve at or near the optic foramen, causing the amblyopia, might depend on the distribution of the nutrient bloodvessels of the nerve, the capillaries in the centre of the nerve being more numerous than at the periphery. On this view sudden changes in the vascularity of the face from exposure to cold, &c., might through the orbito-facial anastomoses lead to congestion and inflammation of the central part of the optic nerve. Mr. Smith referred to a case in point.

Dr. S. WEST read a sequel to a case of Optic Neuritis reported by Mr. Stanford Morton in the Society's Transactions, vol. i. The patient came under Mr. Morton's care in January, 1881. Vision was then perfect, but both discs were greatly swollen; in the following month she consulted Dr. West for headache and for sudden temporary attacks of blindness. Vision began to fail in June, 1881, in the right eye, amounting to J. 2, and  $\frac{1}{200}$ , and the field of vision was much contracted; headache worse. At the end of July, 1881, vision in the right eye was completely gone and was defective in the left. She was very actively treated with mercury and with iodide of potassium on several occasions, but without any good result. In September, 1881, she was completely blind in both eyes. The swelling of the disc remained; atrophy gradually ensued, so that in August, 1882, the discs were quite white and extremely atrophic. In November, 1882, there was no perception of light; the pupils did not react to light, but freely to movements of the eyeball; the eyes diverged but could fix fairly well. The condition was probably secondary to some tumour of the brain, possibly a tubercular tumour, which had become stationary or retrogressive, but the diagnosis was exceedingly difficult. The case was of interest, owing to the persistence of perfect vision for about five months in the presence of extreme optic neuritis, to the attack of temporary complete blindness, to the rapidity with which the failure of vision became absolute when once it commenced, and to the entire absence of any symptoms beyond the eye changes.

Dr. S. MACKENZIE showed a drawing of the Fundus, exhibiting great Tortuosity of the Retinal Vessels, from a patient, aged twenty, who was suffering from severe ves-

emphysema, œdema of the legs, and lividity. The in the fundus of both eyes were extremely tortuous, and somewhat dilated. This condition of the veins, perhaps, have been attributed to the venous obstruction consequent on the emphysema but for the cases recorded lessers. Nettleship and Benson, where the condition was seen in otherwise healthy eyes.—The PRESIDENT had occasionally seen cases, mostly women, of small varicosities of the episcleral region, without impairment of the functions of the eye. In some other cases glaucoma eventually superadded, but he had not operated for fear of hæmorrhage, a which iridectomy shows to be unfounded. In some of the cases the retinal vessels also were enlarged.

Mr. EDMUNDS and Mr. LAWFORD exhibited Microscopical sections of the Optic Nerve from a case of Amblyopia in betes. The patient had been a hard smoker, and sight had been failing for about four months. No ophthalmic changes were detected. He died of diabetes. The section showed changes limited to a group of fibres which extended through the length of the nerve—viz., a thickening of the connective tissue with degeneration of the nerve fibres. Mr. JULER showed again the case of Chronic Membranous conjunctivitis exhibited at the last meeting. The right eye recovered under the use of lapis divinus, but the case had extended in the left.

Mr. J. E. ADAMS showed a case of Chancre of the Upper lip, an indolent shallow ulcer, with surrounding thickening of the under surface of the left upper lid near the outer thus, and a very marked adenopathy on the same side. It was too early to allow of an absolute diagnosis, since no secondary symptoms had as yet appeared.

Mr. GUNN showed a girl with Peculiar Appearances in the Right Retina below the disc, probably congenital.

Mr. ADAMS showed a case of peculiar Congenital Opacity of the Capsule of the Crystalline Lens.

## MEDICAL SOCIETY OF LONDON.

### Microscopical Demonstration of Various Forms of Bacteria.

A MEETING of the above Society was held on the 4th inst., Mr. F. Mason, President, in the chair.

Dr. HENEAGE GIBBES showed a large number of specimens of Bacteria, including bacillus anthracis, bacillus tuberculosis, from cattle and the human subject; the so-called "typhoid bacillus," putrefaction bacilli; bacilli from diphtheria, diphtheria, sheep-pox, purples; bacilli from Welbeck poisoning case; and the so-called infective streptococci from the spleen of a tubercular patient. A great part of the evening was spent in the examination of these specimens. After speaking in detail about the specimens and the mode of preparation employed in the tubercular cases, Dr. Gibbs drew attention to the two forms of tubercle met with in the human subject, as already defined by Klein, the reticular and non-reticular forms (specimens of bacilli both were shown). In the former class of cases bacilli were rarely found; in his own observations in one lung out of ten, and then in the smallest numbers, singly or in groups of three or four in the meshes of the reticulum. In the non-reticular tubercles, on the contrary, bacilli were of almost invariable occurrence in large numbers, and were aggregated into masses especially to be found in the caseous centre. He was inclined to think that the latter form indicated a more acute disease than the former. Bovine tubercle was always of the reticular form, with large and numerous giant cells, the tubercles being aggregated in large masses, which are caseous in many places. In bovine reticular tubercle, however, bacilli were abundant; found, not as in the human subject, solely in the reticulum, but partly round the edge of the caseous region, and partly in the interior of the epithelioid and giant cells. He was inclined to think that this bacillus would prove to be of a different kind from the human one. He had found the bacillus in the liver and spleen, but not in the omentum.—On the motion of the President a cordial vote of thanks was given to Dr. Gibbs for his excellent demonstration; and to Messrs. A. and J. Beck for their kind loan of microscopes.—Dr. C. T. WILLIAMS remarked on the failure, in other hands, of Koch's and Ehrlich's methods of obtaining bacilli, and the universal success of Dr. Gibbs' mode. Had Dr. Gibbs detected the bacillus in the blood? He himself had not been able to do so. By Dr. Gibbs' method he detected bacilli in the sputa of nearly all cases of advanced phthisis,

but not in all. He thought they were most difficult to find in cases undergoing partial recovery.—Dr. R. CROCKER thought Ehrlich's process more successful than Dr. Williams represented.—Dr. HERON said that Koch's process was very difficult, and had been lately abandoned by Koch himself in favour of Ehrlich's process of floating the cover-slip in a solution of fuchsin. Fuchsin is precisely the same thing as magenta, though various specimens of either were slightly different in tint. The cover-slip was washed in nitric acid (one part to two of water), and the specimen then stained with methylene blue. This process, therefore, was practically identical with that of Dr. Gibbs', whom he personally thanked for his labours.—Mr. JABEZ HOGG thought the greatest advantage of Dr. Gibbs' method was that low powers might be used in it. The distinction between various specific bacilli was not at present clear, and it was questionable whether these bacilli of tubercle are really characteristic of this affection.—Dr. GREEN presumed that the Fellows were prepared to assume with M. Koch the essential connexion between the bacillus tuberculosis and the tuberculous processes. Was there, he would ask, any relation found between the number of bacilli and the stage of the disease? He had still to hear what the conditions were which enabled the bacillus to produce its effect.—Dr. GIBBES, in reply, said that he had not examined the blood for bacilli. His method of mixing rosaniline with aniline to form a definite compound was totally distinct from Ehrlich's. Fuchsin would not combine with aniline.

### An Improved Invalid Carriage.—Transplantation of Skin in the Treatment of a Large Hairy Mole.—Talipes Varus treated by Partial Excision of Tarsus.—Bronchiectasis treated by Tapping.

At the meeting of the Society held on the 11th inst., Mr. F. Mason, President, in the chair,

Mr. RICHARD DAVY exhibited an Invalid Carriage he had devised, capable of carrying one, or, at an emergency, six injured persons, in addition to the surgeon and the driver. The carriage was drawn by one horse, and could be shunted on to a steamer or railway-truck; was of large cubical capacity, and admitted plenty of fresh air and light; the door facing a platform for easy ingress or exit. The stretchers are comfortable and strong, and could be easily slung to the roof. Journeys not exceeding twenty miles could be undertaken by road. For the surgeon there is ample space, a floor easily cleaned, and ready means of communication with the driver. A cupboard beneath the driving-box contains surgical requisites and food. Mr. Davy commented on the exorbitant rates and bad accommodation furnished by railway companies, and stated that his carriage had been appreciated by invalids, pointing out the comfort arising from a system that required no change of conveyance in going from one place to another. The carriage was constructed by Mr. Burt, of Swinton-street, W.C.

Mr. W. PYE read notes of a case of a large Hairy Mole on the forehead treated by Transplantation of a Skin-flap from the arm. The patient, who was exhibited, was fifteen months old when admitted into the Victoria Hospital with a very disfiguring hairy mole occupying the right half of the forehead. It was plain that simple dissection or destruction by caustics would involve great risk of deformity to the eyebrow and lid, besides the unsightliness of the resulting scar. It was therefore decided to cover the wound with a flap of skin from the forearm. The flap dissected from the forearm was left attached to the wrist; the mole was completely dissected off, the arm brought up and the flap adjusted to the wound by several sutures. The arm was then fixed in position by strapping and bandaging, and the sides of the wound in the forearm were partly brought together with sutures. Within twenty-four hours the flap had united at all the joints, where it was in contact with the edges of the wound. On the third day, however, the side of the scalp became tumid, and the eye became irritated by the discharge. The flap was therefore detached from the arm on the fourth day, and after a little of it had sloughed the wound healed rapidly. There is now only a fading circular cicatrix marking the place of the original mole. The surgical interest of the case consisted in (1) the method of treatment employed, (2) the fact that the pedicle was taken from the distal side of the forearm with no ill effect, and (3) that the pedicle was divided as early as the fourth day.—Mr. ROSE had lately performed a similar operation on the hand, using

a flap of skin from the abdomen. He divided the pedicle by degrees at the end of a fortnight. Mr. Pye was to be congratulated on the flap living after so early a division of the pedicle.—The PRESIDENT remarked that wounds in children united earlier than in adults. It was fortunate that the child could be induced to keep its arm quiet. He had never divided a pedicle at so early a date. He showed two photographs of cases. In the first, a hairy mole, he had used ethylate of sodium without success, and subsequently nitric acid. In a case of artificial nose he had transplanted a large flap of skin from the forearm to the forehead successfully without any pedicle.—Mr. DAVY had used for many years a very fine needle with thermo-cautery in removing hairy moles in preference to excision. In young infants, however, extensive wounds of the skin might be made without much ultimate deformity.—Mr. PYE said that he had fixed the arm with strapping and bandages, keeping the child under the influence of opium. He thought the mole could not have been removed by the thermo-cautery without leaving a large scar. The mole was raised and deep. He had no alternative between dividing the pedicle and letting the eye slough.

Mr. ROSE read notes of a case of Talipes Varus in a boy aged thirteen, who was successfully operated on by removal of a wedge of bone from the tarsal arch. Casts of the right foot were shown before and after operation, the second cast showing the foot in good position. The patient had been operated on by tenotomy four times at other hospitals without result. The operation was performed antiseptically on April 14th, and the boy left the hospital on June 3rd plantigrade. Mr. ROSE brought forward the case as another link in the chain of evidence in favour of this operation, which should, of course, be restricted to cases in which instrumentation and tenotomy had failed, and where, without this last resource the patient would remain a permanent cripple. The cast of another case was shown, operated on fourteen days ago, the position of the foot and progress of the case being very satisfactory.—The PRESIDENT doubted the necessity of removing so much bone. Did Mr. Davy use Listerism?—Mr. DAVY was glad to see this operation making way, and promised to show some patients operated on by this method at a future day. The insertion of the peroneus tendon was as a rule involved. It was of no importance whether the tendon was cut or not. He did not use Listerism. He had but one death in twenty-five cases.—Mr. ROSE said his patient walked away within two months of the operation.

Dr. C. T. WILLIAMS read notes of a case of Bronchiectasis treated by Tapping. The case was that of a man, aged forty, admitted into Brompton Hospital in April, 1882, with a history of continued cough and expectoration (latterly fetid) of a year's duration following pleurisy. The physical signs pointed to double chronic pneumonia, adhesion of right pleura and numerous bronchiectases of the right lung, the spots of gurgling being seated in the second and third interspaces near the shoulder, in the fourth and fifth outside the right nipple, and posteriorly near the lower angle of the scapula. Antiseptic measures failing to reduce the fetor, Professor Marshall, at Dr. Williams' request, made a vertical incision from the fourth to the sixth rib, along a line marked out by the latter, and plunged a trocar and director (specially devised by Dr. Hicks) to the depth of four inches in the direction of the root of the lung. Air hissed out of the opening, and a quantity of fetid matter and sloughing debris was forcibly ejected. The opening was enlarged and a drainage-tube inserted. All fetor ceased, the cough moderated, the temperature fell to normal, and the patient took exercise in the garden. Nineteen days later the discharge increased and became thoroughly fetid, the temperature rising to 101.4°; there was some headache. The discharge continued, but became fetid; vomiting, followed by drowsiness and left hemiplegia, ensued, and death by coma took place on July 6th, forty-five days after the operation. An abscess was found in the left cerebral hemisphere; there was chronic pneumonia, an adherent pleura in the left side, and numerous small bronchiectases, as well as some larger ones, in the left lung, the largest, of the size of an orange, having been the one tapped. No tubercular or caseous masses were found. The case illustrated the difficulties of dealing with bronchiectasis, especially of the globular or saccular variety. By loss of their contractility the tubes were converted into mere bags of putrescent matter, which became absorbed and caused pyæmia. The diagnosis was tolerably exact, and, fortunately, the largest bronchiectasis was reached without much difficulty, and the first results of the operation were thoroughly satis-

factory. He alluded to the value of a vertical skin incision over two interspaces, to allow, if necessary, a second puncture into the adjoining space, and to Dr. Hicks' director attached to the trocar and cannula, which enabled the opening to be readily enlarged for the introduction of the drainage-tube. This was the fourth case of bronchiectasis which Dr. Williams had tapped, but was the only one where death ensued from cerebral abscess; in two others septicæmia of the opposite lung was the cause. One patient was still living after two years' interval, but the chief difficulty lay in the number of operations which were sometimes necessary to establish efficient drainage.—Dr. SYMES THOMPSON said that the difficulty in these cases was that the dilatations were seldom single. In one case Dr. Williams had made as many as six incisions. The irritation of retained secretions could not be successfully overcome by inhalations.—Mr. E. OWEN asked whether Listerism was essential to these cases. In a case he had recently operated on for Dr. Broadbent, excellent results had followed without it. Was it worth while keeping germs from the wound while they could enter by the bronchi?—Mr. HUBERT SMITH thought antisepticism useful when pleural adhesion had not taken place.—Dr. WILLIAMS, in reply, said that in such cases something must be done, otherwise the fetor would render a hospital uninhabitable. He had left the surgical treatment of the case in Mr. Marshall's hands. Free drainage was the main point. It was his first care before operating to ascertain that the pleural layers were adherent.

#### MIDLAND MEDICAL SOCIETY.

AN ordinary meeting of this Society was held in the Birmingham Medical Institute on Wednesday, November 22nd, Dr. MALINS, President, in the chair.

Dr. MALINS showed a large Cyst of the Broad Ligament successfully removed by Abdominal Section.

Mr. KENNETH MILLICAN (Kineton) exhibited some specimens of Bacilli from cases of Diarrhoea which were found in the stools of patients affected during an epidemic. The motions were not unlike those of typhoid fever, and contained small gelatinous lumps. A cover-slip smeared with these lumps, dried and then stained with aniline blue, exhibited the organisms. An interesting therapeutical point was that the diarrhoea, which resisted all ordinary methods of treatment, yielded in about twenty-four hours to the internal administration of carbolic acid and terebene, the former being given in one and one and a half grain doses every two hours, the latter in doses of from five to ten minims.—Mr. MILLICAN also showed a specimen of Bacillus Anthracis.

Dr. A. H. CARTER showed specimens of the Bacillus Tuberculosis prepared by the method of Dr. Heneage Gibbs.—Mr. MILLICAN, referring to some remarks as to the diagnostic value of the bacillus tuberculosis, said he considered Dr. Heneage Gibbs' method absolutely diagnostic for the following reasons:—(a) It stained the bacillus tuberculosis clearly, and did not affect the organisms found in phthisical sputum. He had tried Ehrlich's method and several stains of his own, but found that, while they certainly brought out this particular organism, they obscured the diagnostic value by bringing out also the organisms and putrefactive bacteria. Having assured himself that these organisms were present in the sputum, he then used Gibbs' method, and found that only the bacillus tuberculosis appeared. (b) On employing Baumgarten's method—viz., immersion in a 33 per cent. solution of caustic potash—he found this rendered the bacilli visible; afterwards by staining with Gibbs' process it was found that all the organisms took the stain. (c) He failed to make Heneage Gibbs' stain dye the organisms from epidemic diarrhoea, stale sputum, and stale hay infusion until after they had been immersed in the 33 per cent. solution of caustic potash; they then stained readily.

Dr. SIMON showed a series of living cases of Extensor Paralysis.

Dr. SAVAGE showed two specimens of Double Pyosalpinx which he had recently removed from two young single women. There had been a long history of pain, and in one of the patients anæmia and a high temperature, 104°. The tumours were each about the size of an orange. During removal of the tumours rupture occurred, and there was a considerable escape of pus into the pelvis; this was cleaned

, and a drainage-tube inserted. The operations were not formed antiseptically. The patients did well.

#### *The Notification of Infectious Diseases.*

Mr. J. H. PALMER (Solihull) in moving the following resolution, "That this Society, recognising the necessity for isolation to provide for the better notification of infectious cases, is of opinion that the duty of making such notification should devolve upon the occupier of the house and not on the medical attendant," said that the expediency of providing legislation for the better notification of infectious cases had occupied the attention of the profession, with whom the idea had originated, and of the public. In many private Bills which had passed into law powers had been conferred upon sanitary authorities to enforce which no one would dare to attempt. The Bill introduced by Mr. Hastings was sound in its object but faulty in detail. The duty of making the notification was one which obviously devolved upon the occupier of the house. In the Bill brought for Ireland the duty of notifying was rendered compulsory on the occupier and permissive on the part of the medical attendant; that seemed the prudent course. Mr. Hastings' proposal that the matter should go to a Select Committee was a fair one, and showed that Mr. Hastings was quite prepared to see the question discussed in all bearings.—Dr. GRIFFITHS seconded the resolution.—ALFRED HILL in moving an amendment combated the objection raised by the opponents of notification by medical men, such as compulsion and its alleged consequences—viz., antagonism between the medical attendant and the medical officer of health, the inquisitorial character of the duties of the latter in some cases, and the spread of disease from concealment. He showed that in many towns where the Acts had been put in operation the evil predicted had not followed, and the best results had been attained. Compulsion of the householder had been tried in Greenock for five years, and had failed to achieve the amount of good to be expected from a compulsory system of notification. Nothing but notification by the medical attendant, either with or without the same on the part of the occupier, would be of use. He concluded by moving the following amendment:—"That this Society, regarding the views of the leading sanitary authorities, that early notification is necessary for the control of infectious diseases, and having the benefit of the experience of the large number of towns which have already put the Compulsory Notification Act into force, is of opinion that every sanitary authority should possess parliamentary powers to obtain notification from both the medical attendant and the householder or person in charge."—Dr. WILSON (Leamington), seconded the amendment, and said there could be no doubt that outside as well as inside the profession there was a steadily growing conviction that a systematic or efficient control of dangerous infectious disease was possible without early notification, and that early notification could not be uniformly obtained unless under legal compulsion. It was quite true that the experiment had been tried in various quarters, and in a part of his own district, of entering into an agreement with medical practitioners to report all cases of certain specified diseases on payment of a stated fee; and though he admitted that the experiment, so far as his experience went, had succeeded admirably, he felt sure that it would not succeed in any locality of limited area and population where the medical officer of health was allowed private practice, and could thus enter into competition with his medical brethren. He felt convinced that there could neither be promptitude or efficiency in notifying unless the medical attendant was made responsible, although he maintained at the same time that any measure would be faulty and one-sided if it did not render the householder liable to heavy penalties if he failed to report.—Mr. GAMGEE spoke in favour of the resolution.—Mr. HENRY MAY (Aston) supported the amendment.—Mr. H. R. KERR (Halesowen), while believing compulsory notification to be necessary, objected to the proposal being thrown on the practitioner.—Mr. HALL WRIGHT believed that in refusing to notify the members of the profession would be doing an injustice to themselves and to the public by shirking a responsibility that it was their duty to take.—Dr. A. H. CARTER thought there was an official and professional side to the question, and that the members of the profession had not been treated well in the matter. The Birmingham Town Council were about to apply for a Bill compelling professional notification, and he thought that a

deputation should attend upon that body before the initiative was taken.—Mr. PALMER, in reply, stated that he regarded compulsory notification as the thin end of the wedge. The amendment was then put, and carried by a large majority, and subsequently as a substantive resolution.

#### NORWICH MEDICO-CHIRURGICAL SOCIETY.

THE second meeting of this Society was held at the Norfolk and Norwich Hospital on Dec. 5th, the President, Dr. Barnes, in the chair.

Dr. EADE showed a specimen of a Phlebolithe, the size of a hazel nut. A lump had existed on the lower part of the right leg of a woman for thirty or forty years, ulceration occurred, and the concretion was discharged; it weighed twenty-nine grains. The portion insoluble in water consisted of phosphate of lime, with traces of phosphate of magnesia and some carbonates; the soluble portion consisting of the chlorides of sodium and ammonium, and some sulphates.

Mr. D. DAY exhibited a Dissection of a Double Fœtal Monstrosity, of which the following is a brief description. The heads and limbs are perfectly formed. The bond of union is the front of the thorax and upper part of the abdomen. The ribs are united on each side to a complete sternum, which is symmetrical; the lungs are normal; and there is one umbilical cord. The heart is single, in a single pericardial cavity; the auricles are distinct, the ventricles completely blended; the vessels at the base are quite distinct; and there are two inferior venæ cavae. The diaphragm and liver are common to both. Close under the liver are two stomachs, the intestine beginning by a fusion of the two pylori; for sixteen inches it is single, it then branches into two, and the remainder of the intestines run a normal course. The umbilical veins divide as soon as they enter the abdomen, half going to each side.

Dr. BATEMAN showed a specimen of Ovarian Disease, complicated with Hydatids of the Liver. Against advice, the woman persisted in going to the w.c., and was there seized with an attack of syncope, from which she died.

Dr. MALLINS recorded a case of Jaundice, caused by a round worm obstructing the common bile duct.

Mr. LYDDON reported a case of Removal of Foreign Bodies from the Ears after twenty years' impaction; from one ear a pearl button, and from the other an iron dress-hook, where removed by iridectomy forceps. No structural changes had taken place in either ear, and the hearing was perfect.

Mr. H. TURNER read notes of a case of Rheumatic Fever which, while apparently progressing satisfactorily, terminated fatally in two hours, with cerebral symptoms (the patient was taking fifteen grains of the salicylate of soda every six hours). The cause of death was believed to be meningitis.—Dr. EADE also described three cases, with cerebral symptoms, he had seen in consultation about the same time (September), no cases of the kind having occurred in his practice for several years.

#### Reviews and Notices of Books.

*Report on the Scientific Results of the Voyage of H.M.S. "Challenger" in 1873-76, under the Command of Captain George Nares and Captain Frank Thomson. Prepared under the superintendence of Sir C. WYVILLE THOMSON, F.R.S. Vol. III.: Zoology. London: Longmans and Co.; John Murray; Macmillan.*

THIS volume contains a report on the Echinoidea, dredged in the course of the voyage, by Alexander Agassiz; and a report on the Pycnogonida, by Dr. P. P. C. Høek, assistant at the Zoological Laboratory of Leyden University.

Agassiz states that a careful comparative study of the new species collected by the *Challenger* and by the *Blake* seems to make a short revision of some of the principal lines of the recent and fossil Echinids desirable, as, from our present knowledge of the affinity of the Echinoidea, several groups formerly considered somewhat aberrant can now be shown to be closely connected. The consideration of this group

could have passed into no better hands than those of Alexander Agassiz, for he possesses an extensive acquaintance with both the recent and fossil specimens, and has himself examined all but a few of the deep-sea species, whilst he has had the further advantage of describing the first important collection of deep-sea echinids made by Count Pourtales. He holds that the artificial classification of the Echinoidea at present accepted is unsatisfactory, because based upon characters of such uncertain value as the presence or absence of teeth and of actinal cuts. He founds his classification of the echinids on that of Lovén, which he regards as by far the most ingenious that has yet been proposed, and who has suggested a most admirable notation to denote the several ambulacral and interambulacral areas, which simplifies to a remarkable degree the comparison of the various types. The number of fossil species is about 2000, whilst there are not more than 300 recent, and about one-third of the whole number of known species have been discovered since the days of deep-sea dredging; but the difficulty of tracing the genealogy of these is almost insuperable, for, as he shows, the number of variable terms are at least twenty—viz., the apical system, the actinal system, the genital, ocular, anal, and coronal plates, the ambulacral and interambulacral areas, the poriferous zone, the primary, secondary, and miliary tubercles and their corresponding spines, the modifications of the poriferous zone near the apical and actinal systems and on the test; the fascioles, jaws, alimentary canal, the position of the apical system, of the anal system, of the actinostome, and the modifications of the same; and when we consider that these may be combined in all possible ways, it is hazardous, to say the least, to attempt anything beyond the broadest indications of the outlines of the relationship.

The study of the Echinids dredged by the *Challenger* has shown very plainly the antique character of many of the deep water species, and their resemblance to Cretaceous genera, and Agassiz points out many noteworthy relationships. He remarks that in comparing the Tertiary fossil Echinids of the European beds with the species now living in the West Indies, it is impossible to avoid being struck with the similarity existing between them. Thus the species of *Cidaris*, *Clypeaster*, and others, which are found in the Tertiary beds of Malta, are no longer found in the Mediterranean, having undoubtedly disappeared from that sea as soon as it became closed, and the temperature of the water became raised above that of the ocean; while, on the contrary, where the oceanic conditions have not undergone any great change, we find a remarkable identity in the genera of the Tertiaries and of the surrounding deep sea, as can be easily seen by comparing the Tertiary West Indian types of *Echinolampas*, *Agassizia*, *Brisopsis*, and others, with the species of the same genera now found in the deep waters of the Caribbean Sea and Gulf of Mexico.

The number of deep sea species discovered by the *Challenger* appears to have been forty-nine, whilst forty-one were discovered by the *Blake*, *Porcupine*, and *Josephine*. The plates are sixty-four in number, many of them representing several forms.

We must refer to the original for the descriptions and beautifully executed lithographs of the numerous new species collected by the *Challenger* and the *Blake*. Many interesting facts are related in the account of each genus and species. Thus, under "*Goniocidaris*," he quotes Thomson's "*Voyage of the Challenger*," to the effect that the eggs, after escaping from the ovary, are passed along on the surface of the test towards the mouth, and the smaller spines articulated to the tubercles round the peristome are bent inwards over the mouth, so as to form a kind of open tent, in which the young are developed directly from the

egg, without undergoing any metamorphosis until they have attained a diameter of about 2.5 mm. Even before they have attained this size the more mature or more active of a brood may be seen straying away beyond the limits of the nursery, and creeping with the aid of their first few pairs of tentacular feet out upon the long spines of their mother; after a short ramble they return to the marsupian.

In regard to the Pycnogonidæ the results of the *Challenger* dredgings are most satisfactory, for it appears that of the forty-one species obtained during the voyage of the *Challenger* and the cruise of the *Knight Errant*, thirty-three are new to science, and of the nine genera represented three are new. The pycnogonidæ are long-limbed aquatic animals, distantly resembling a spider or a "daddy longlegs," or a spider crab. They breathe by the general surface of the body, which body consists of a cephalo-thoracic segment, three thoracic segments, and rudimentary abdominal segment. They have a proboscis and three pairs of cephalic appendages, of which the first represents antennæ, whilst the two others are post-oral. The thoracic part of the cephalo-thoracic segment and the three thoracic segments are each furnished with a pair of long eight-jointed legs, into which the alimentary canal sends off long cæca. The nervous system shows a supra-oesophageal and five thoracic ganglia. The eyes are feebly developed in the deep water species, but rather highly developed in the shallow water species. The sexes are separate. The paper is illustrated by twenty plates, seven of which are devoted to the elucidation of the internal structure of this curious group of animals.

*Nice and its Climate.* By Dr. A. BARÉTY. Translated, with additions, by CHARLES WEST, M.D.; and an Appendix on the Vegetation of the Riviera, by Professor ALLMAN, F.R.S. 8vo, pp. 160. London: Stanford. 1880.

THIS volume is one of a class which we should be well pleased to see multiplied. It has been written, not with a view to extol Nice as the only suitable winter resort for invalids, but with the desire to furnish the profession with reliable information on the subject of the climate, and its therapeutic effects upon different diseases. With this object Dr. Baréty first gives an account of the essential conditions governing the climate of Nice; the invariable, as topography, soil, air, &c., and the variable, including the temperature, barometric pressure, winds and rainfall, and its suitability for invalids. In this portion of the book he lays down some excellent hygienic rules, which well deserve the perusal of all medical men who send patients abroad for change of climate, and the careful study of all who are obliged to seek winter health-resorts. "They who come to Nice for their health must not forget the risk to which a participation in these pleasures [the opera, the theatre, concerts, and balls] exposes them, and, if they are wise, will consult their medical attendant as to the degree in which they may indulge in them, as much as concerning the remedies they should employ, or the regimen they should observe." He then proceeds to a consideration of the influence of the climate as a remedial agent, pointing out in detail the class of cases likely to derive benefit from residence in each of the three climatic zones into which he divides the territory of Nice, and especially its influence on the various forms and in the different stages of phthisis. In the third part, comprising a description of Nice and its neighbourhood, Dr. West has, by permission of M. Lenthéric, incorporated the description given in "*La Provence Maritime*" with that of M. Baréty, and has thereby added much to the value of the work as a guide-book. He has also, with the consent of the author, appended a sketch of the vegetation of the Riviera contained in Professor Allman's anniversary address as President of the Linnæan Society in 1880. The book has been translated by Dr. West with that care which always characterises his work, and he has added to its value by the notes he has interpolated.

*Madeira: its Scenery, and how to see it.* With Letters of a Year's Residence, and Lists of the Trees, Flowers, Ferns, and Sea-weeds. By ELLEN M. TAYLOR, 8vo, p. 261. London: Stanford. 1882.

THIS volume does not treat of Madeira from a professional point of view, nor does it afford any information as to the influence of its climate upon disease, but it is an excellent book for visitors to the island, or for those who desire to make a more prolonged residence in it. It contains all the necessary information as to the means of getting there, the mode of life in hotels, lodgings, or a hired house. Details are given to enable the visitor to make excursions to all the most beautiful parts of the island, and the volume abounds in information respecting its flora. In addition to a good description of Funchal and of its various public institutions, there is much that is interesting respecting the past history of Madeira. The volume appears remarkably well adapted to the purpose for which it was written—that of a handbook which will furnish all the information necessary for a stranger visiting, or intending to reside in, Madeira either for health or pleasure.

*Physicians' and Surgeons' Visiting List, Diary, Almanack, and Book of Engagements for 1883.* Thirty-seventh year. London: John Smith and Co.

THE return of Christmas reminds us that we must renew our visiting lists, than which nothing contributes more to the easy and methodical discharge of medical duty. Of no one holds its ground better than Smith's, which this year, amongst its new features, has a useful list of so-called "American Eclectic Remedies" and other doses, which is always to be found in available works of materia medica. The doses of remedies do not always correspond to those given in the Pharmacopœia. Sometimes a larger dose is recommended than that of the Pharmacopœia, as in the case of ext. nuc. vomic.; sometimes a smaller, as in the case of tinct. conii. We think it would be better to give the Pharmacopœial doses. The book is full of useful tables, including one of corresponding degrees on different thermometric scales, one of days of incubation of eruptive fevers, and is altogether too well known to need further commendation.

### THE LATE SIR THOMAS WATSON.

ON Friday, the 15th instant, the remains of Sir Thomas Watson were conveyed in a plain coffin of polished oak, without other covering than a large floral cross, from the residence of his son to the burial-ground attached to the gate parish church. At the entrance of the churchyard a procession was met by the clergy and a surpliced choir, who chanted the opening sentences of the service. The latter part of the service, including the singing of the two well-known hymns, "Lead kindly light" and "Ten thousand times ten thousand," was performed within the church. There was afterwards a procession to the grave, the bare top of which had been concealed from view by a lining of greenery and flowers. Amongst those forming the procession were the son and heir of the deceased Sir Arthur Watson, Lady Watson, Miss Watson, the two sons and two daughters of Sir Arthur and Lady Watson, and Captain Watson, a nephew of Sir Thomas. The medical attendants of the deceased were all present—namely, Dr. Walters, George Johnson, Mr. Lister, Dr. Greenhow, and Dr. Leman. The College of Surgeons was represented by the President, Mr. Spencer Wells, and the College of Physicians by the Registrar, Dr. Pitman. Sir William Jenner wrote to express his regret that he was unavoidably prevented from attending. The attendance of many London physicians and surgeons

was prevented by the distance from town, and by the wintery weather, which deters many elderly and not over-robust men from attendance at a funeral. Sir James Paget was prevented from attending by an important engagement at the College of Surgeons.

The remains of the revered physician rest near those of his sister, who died about two years ago. In the brief written instructions which he left he chose this as the place of his burial, since he could not, as he would have wished, be buried by the side of his wife, whose remains, in September, 1830, were deposited in a burial ground at St. John's-wood, which has since been closed.

The Rev. Mr. PAGE ROBERTS, preaching last Sunday in St. Peter's, Vere-street—a church so much frequented by medical men as to have received the name of "the Doctor's Church"—said: "The life of a good man is moral vitality poured into the blood of the next generation. Such a life as that of Sir Thomas Watson is a blessing diffusing itself through humanity, and is still more influential in the profession which he adorned. I am but little fitted to pay a worthy tribute to his memory. A misfortune I shall ever consider it that my acquaintance with him was but short and my intercourse with him intermittent. In this church there are many more fitted than I to do him honour. In one way only am I as fitted as they, and that is in as tender and reverent a devotion to his memory. I know not what he was in the maturity of his powers, but in advanced age he put forth a spell of fascination, and 'virtue went out of him.' There are some words of his with which he concluded his lectures on the Principles and Practice of Physic which reveal his character—'That by the humane exercise of our noble calling you may do good in your generation to others, and so to yourselves, is my earnest desire and prayer.' Here we have the spirit in which he held his calling should be fulfilled, and the piety which was the natural breathing of his mind. His calling he felt to be noble; it concentrated his energies and filled his mind, and made him always do his best. In his own words, he felt it 'worthy the devotion of a lifetime.' He could not degrade that high calling by pretence of manner and remunerative plausibility. If ever a man was unstained by charlatanism and unacquainted with the arts of a properly qualified impostor, it was Sir Thomas Watson. In the minutes of a life of a once famous doctor and still prized man of letters—Sir Thomas Browne—whose 'Religio Medici' will be read with pleasure when most of the popular books of to-day are forgotten, his biographer says that 'had it been his province to preach his funeral sermon, he should have taken his text from an uncanonical book. Honour a physician with the honour due to him for the uses which ye may have of him: for the Lord hath created him. For of the Most High cometh healing, and he shall receive honour of the King. The skill of the physician shall lift up his head, and in the sight of great men he shall be an admiration' (Ecclus. xxxviii. 1, 2, 3). Sir Thomas Watson was a physician indeed, and the honour he received was his due. The distinguished members of his own profession did him reverence; rivalry was impossible in the presence of such open-minded modesty. 'Quite the right man' said the Prince Consort of him, with his keen perception, as he lay upon the bed from which he was no more to arise, and from his Sovereign he received that gracious recognition which men who do worthy work so justly prize, and to the last that rewarding notice never failed. His noble calling Sir Thomas Watson exercised 'humanely.' There are members of it who are charged by some with inhumanity, because, in the service of humanity they seek knowledge by methods which many sensitive minds condemn. Give me the freedom of opinion which you all take for yourselves, and I must say I cannot charge such servants of humanity with inhumanity because they put men first, and subordinate all below man to his well-being. Wanton cruelty, I am sure, is rare, and is worthy of condemnation. The cruelty of unfertile

curiosity cannot be frequent among men who know too much of pain, and are too eager to alleviate it willingly to inflict it. I am convinced that Sir Thomas Watson, profoundly humane as he was, would not have dissented from this opinion I have been so bold as to express. But when I use his own word 'humane,' I mean that he was benignant. He had a graciousness, a sympathy, a quickness to understand, a liberal openness of mind, and a gentle, assuring courtesy, which gave courage to those who came to confide in him, and at least did somewhat to alleviate the alarms which add fresh burdens to those of disease. He could not be ill-mannered; he could not forget what was due to others; above all, he was a deeply religious man. 'It is a common speech,' says an old writer, 'ubi tres medici duo athei.' Three doctors, two doubters. But it is not hard to explain why doctors are regarded by people who do not think as indifferent or opposed to religion. Very often they have had to set themselves in opposition to teachings and practices which were connected with religion, and thus they were held to be attacking religion itself. The very moment medicine began to distinguish itself from magic, that moment it must have excited the enmity of the professors and practisers of magic, who were generally priests. 'Doctors,' says Mr. Mathew Arnold, 'are the natural friends of lucidity,' and he defines lucidity as 'the perception of the want of truth and validity in notions long current, the perception that they are no longer possible, that their time is finished, and they can serve us no more.' Rational medicine became possible when at length charms and incantations were seen to be worthless, and rational medicine must at first have been looked upon as a rebellion against religion. Then, again, the study of physical science, which includes that of the human organism, was looked upon for generations with suspicion, and Christian ecclesiastics, and even a Pope, fell under suspicion of heresy, because of his scientific investigations. The same dark shadow could rest upon the doctors and would do much to deter earnest Churchmen from adopting the medical profession. It fell, therefore, into the hands of Jews and Arabs, among whom lived on the traditions of Greek schools and freer days; and it has been said that 'in the eleventh century nearly all the physicians in Europe were Jews' (Draper). But Arabs and Jews, to the Church, were infidels—in other words, doctors were infidels; and men have gone on saying this, or something like it, until the present day. But, speaking from a fairly large experience, I should say the contrary. Instead of less, I have seen more reverence and piety of soul among doctors than among other classes of men. And I should naturally expect it. 'These men see the wonders of the Lord.' Foppery and frivolity may have no feeling, and fools may say there is no God; but intellectual eminence gives a man a vision denied to the vacant and the idle. Sir Thomas Watson was a truly and unaffectedly religious man. For many years, how many I know not, each Sunday saw him in this church, and to the last his venerable devotion was expressed at the Lord's table. Various were the sides of truth which were presented to him in the ministry of this church, but I am sure that to all he gave the consideration of a temperate and unprejudiced judgment. That which he could take he took, and at least his prayers always overshadowed him with benediction. 'I have no genius for disputes in religion,' he might have said, with Sir Thomas Browne. 'He was a man of peace, and the blessing of the peace-maker is his.' 'The profession of medicine,' he said, 'having for its end the good of mankind, knows nothing of national enmities, of political strife, of sectarian divisions.' I cannot more fitly close this sermon than in words of his own which were spoken on the death of his friend Dr. Peter Mere Latham, and which I will say of himself, 'Ripe in years and ready in spirit for the solemn change, his death must long be the subject of tender and sacred regret among the nearest and dearest of his surviving friends; nor will his memory soon cease to be reverently cherished throughout a much wider circle.' Not as 'water spilt upon the ground,' is the life we seem to have lost. His are the two immortalities which are granted to the good. And specially let me say to you members of the medical profession, to so many of whom it is my great privilege and responsibility to minister, that life of nobleness is still with you, and will be with those who shall come after you, even when no conscious memory of it remains; and that you, too, may reach that high life over which death hath no dominion, is the earnest desire and prayer of your friend and pastor."

## DR. MOXON'S LECTURE ON

To the Editor of THE LANCET

SIR,—Will you grant me space while what appears to me a needful remark Moxon's attractive lecture on "Fever," read in your issue of Dec. 2nd.

I allude to his criticism, severe in form gentle, delivered on a definition of "fever" which the lecturer and most of us recent work on medicine." And he begs Moxon's pardon if I wrongly take his criticism, as his many readers have done, to be a criticism of the lecturer and not of the book. I plead, as my reason for writing, the temptation to counteract the very false impression produced by this somewhat plausible work.

In a passage reminding one a little of an examination, Dr. Moxon treats the definition of fever which he appears to allude to, as follows: "By that abstract condition which is called febrile disorders, and the presence of which is claimed to that designation"; and the writer of the confessedly useful work, including in the terms of his definition, to be defined. But an accurate definition deprives that seemingly formidable terror. Dr. Moxon's edition of the work is perfect; garbled unintentionally, inverted commas (in this instance) are ignored; imperfect, in that the definition is altogether omitted. The author's own statement: "By that abstract condition which is called febrile disorders," and the presence of which is claimed to that designation. Essentially of temperature, the immediate elevation, and the consequence entail." A moderately careful reader that Dr. Moxon has resorted to the classical device of setting up the term "so-called febrile disorders" in this well-known book on medicine to express conveniently the typhoid, variola, scarlatina, &c. the words "so-called" and the term "febrile disorders," Dr. Moxon. Had the author of his list of diseases explicitly, in grouping mark or formula, the never have been shot at all, for formal plausibility that it now passes for a book as it stands is certainly guiltless of any logical flaw.

For his well-timed and brilliant and unsavoury medical bulletins to the reader, as a necessary consequence, Dr. Moxon has a confession at large. Such a confession have sounded farther and more in the midst of the digressions ordinary and very interesting lecture.

I am,

Upper Berkeley-street, Portman

PROVIDENT SURGICAL the 14th inst. the decennial in the Cannon-street Hotel. the toast of the evening, at the practice to extend aid obtaining the requisite number applicants were relieved of requirement. During the 25,000 surgical appliances course of the evening the was announced,

# THE LANCET.

LONDON: SATURDAY, DECEMBER 23, 1882.

THE action of the English Royal Colleges in the direction of combining for the establishment of a complete conjoint medical and surgical examination continues. As we reported last week, the Council of the Royal College of Surgeons has elected seven delegates to confer with an equal number of representatives of the Royal College of Physicians. The presence of the members chosen by each body is a further proof of the earnestness of these corporations. Many persons think that in the circumstances of the present moment, if a Government disposed to legislate on the lines of a Royal Commission appointed by itself, and a case ripe for legislation, the Royal Colleges might have waited a few weeks for the final decision of the Government. The English Corporations, and notably the Royal Colleges, have shown a great deal of public spirit and disinterestedness of late years in urging legislation to compel the formation of a Conjoint Board in each division of the kingdom. It would have been natural for the English Royal Colleges to assume that the conjunction which they have all along advocated was about to be accomplished with the help of a strong Government and the concurrence of a large majority of the profession. But it would seem that they see nothing in the actual situation to forbid them from preparing to co-operate. It is undeniable that in itself the conjunction of the Royal Colleges will be a good thing. It will unify the portal by which the majority of English students enter the profession. It will abolish, as far as England is concerned, the system of half-qualifications, which has had an absurdly long life, and which, when once abolished, will be regarded still more absurd than it even now appears. There is nothing, too, in this projected Board which has great significance and satisfaction for medical reformers. One corporation will be conspicuous by its absence in it, and will, in fact, be quietly dropped out of existence. The Apothecaries' Society will become a thing of the past as far as the medical profession is concerned. Having lived to do duty neglected by the College of Physicians, its *raison d'être* disappears when the College resumes its duty. It will, indeed, remain open to anyone desirous to label himself apothecary to repair to "the Hall," as his forefathers have done for a couple of generations, but few such pilgrims will be found among those who succeed in obtaining the diploma of the conjoined Colleges. We take this disappearance in England of an altogether superfluous corporation as an earnest of what will happen both in Scotland and in Ireland.

But whatever may be the good done by the conjunction of the Royal Colleges in England, there is one thing that it will not do—it will not supersede the necessity for legislation; it will not remove the competition downwards of rival Bodies or of rival Conjoint Boards. A conjunction of Royal Colleges is in itself no guarantee of a satisfactory examination. The examinations of the Conjoint Corpora-

tions of Scotland have suffered in reputation more than any other examinations by the ordeal of inquiry of the Royal Commissioners. Even if the examination of the English Colleges were in itself satisfactory, there would be no guarantee that the examination of the Conjoint Boards of Scotland would be equal to it. The very excellence of the English examination might and would drive men elsewhere to an easier one, so long as it can be found. And it will be found till legislation reduces the number of Boards to three, that can be easily supervised, and provides other securities for a rough equality in the licensing examination of each division of the kingdom. So far, then, from the creation of such a Conjoint Board as is contemplated by the two Colleges in England superseding legislation, it will increase the urgency of the need for it.

THE time has arrived when it is necessary, in the interests of public safety and professional honour, to speak out on the subject of the employment of "unqualified assistants." We are not insensible to the exceeding difficulty of the position in which a considerable section of the medical fraternity is placed. Poor-law appointments are so miserably salaried, and the lives of medical practitioners in many districts are so hard, and involve so great a struggle to make both ends meet, that it will be a very heavy tax on the profession as a whole, and a crushing burden on many of its most hard-working members, to put an end, once and for all, to the employment of unqualified assistants. Nevertheless, the sacrifice should be made. It is unfair to the sick to place their welfare and even their lives at the jeopardy of unskilled treatment, and it is not consonant with the honour of our high calling to allow patients to suppose they are receiving qualified advice and assistance, when, as a matter of fact, they are being attended by incompetent, or at best unlicensed, practitioners. The profession as a whole has no adequate notion of the extent to which the employment of unqualified assistants has been carried. In many of the "populous districts," and lower neighbourhoods of our large cities and towns, from the metropolis downwards, the bulk of the heavy work has been done by persons of this class, either under the guise of studentship, apprenticeship, or some such flimsy pretence. This is a great evil, and we are glad that attention has been publicly called to the matter, so that it only now needs a little earnest and plain speaking to secure its discontinuance before worse troubles than those which have already arisen occur.

One of the difficulties which will attend the endeavour to reform the mode of practice by unqualified representatives—and it must be reformed altogether, and quickly too,—will be found to lie in the danger and disadvantage of extinguishing the class of "private pupils." Although apprenticeship has almost died out, there has been, and is, a widespread clinging to the notion that youths ought to be trained to the art and mystery of medicine by the personal tutelage of a practitioner. We must confess to a strong belief that this notion is well-grounded. Young men who have never done more than attend lectures, dissect, and "walk the hospitals," to use an old-time phrase, are not initiated into the detailed work of a "practitioner"; they can really know nothing about *private* practice. How should they? Except by hearsay they can have no possible acquaintance with the

routine work of the busy family attendant. A thousand and one little questions of personal treatment—many of the highest practical moment—never crop up at a hospital, especially a hospital conducted on the modern principle, with a “nursing” department administered by women. We may go further, and assert that the great bulk of minor maladies, such as those of children and women, the “colds,” teething-troubles, nursing-difficulties, and such simple ailments as infantile diarrhoea, tooth-rash; and even measles, whooping-cough, the mumps, and slight but troublesome gastric disturbance, are not seen at the hospital! These minor maladies are many, and constitute a vast *terra incognita* to the college and hospital trained student. He knows no more—can know no more—of them than a modern art student knows of the business of grinding and mixing his own colours. There is only one way of learning the practical business of “a family doctor,” and that is by direct personal observation and training under a practitioner. Not even dispensary practice—excellent as that is in its place—will suffice to qualify the tyro in medicine for the work before him as “a general practitioner.” It is a matter of daily observation and experience that the men who have had the training to which we point are incomparably better furnished for the discharge of medical duties, even in the highest walks of the profession and the most exclusive practice as consultees, than those who have begun at the top of the ladder and undertaken the onerous and difficult task of giving advice to others before they have first mastered the rudiments of their professional work, and gathered *experience*—for the lack of which nothing else can possibly compensate—by acting under personal direction and being advised.

Now, it must be obvious that if young men are not to practice until they are qualified, some arrangement will have to be made by which a term of supplementary final pupilage may be entered upon immediately after passing a qualifying examination. To the adoption of this method we have often pointed in THE LANCET. It would be an admirable and convenient plan for young men entering the profession to pass some months in the service of a general practitioner after the first qualification has been obtained. If this practice should find favour with students, one great difficulty in the way of wholly discontinuing the employment of unqualified assistants would be removed. We do not think the services of those unfortunate men who, having failed to “pass,” hire themselves out as “unqualified assistants,” are so highly valued by the profession as some writers on this subject seem to suppose. Practitioners would gladly get rid of the unsatisfactory representatives to which we refer if only they could obtain the aid of young qualified men fresh from the schools. We look to this solution of the difficulty for a way to the needful reform.

A DISTINGUISHED German pathologist, Dr. AUFRECHT, has for some time maintained the opinion that all forms of diffuse nephritis begin in a similar manner; and that in all, even the interstitial variety, the inflammatory process is essentially “parenchymatous,” and starts from the epithelium of the glomeruli and urinary tubules. In support of this view, he published some time ago a series of experi-

ments on temporary ligation. The first effect was to be became granular and clotted. During the first few days the kidney was perfectly normal. There was a dilatation of the cellular elements between the cells of their nuclei. Subsequently the process became increased in thickness, swelling of the adventitial tissue. At the same time further changes in the epithelium of the urinary tubules became transformed into small, visible nuclei. They did not, although the interstitial tissue bulk in consequence of the cell multiplication, with a consequent dilatation of the lumen of the tubules. Thus a morbid process was set up, but beginning distinctly in the interstitium. REIGERT has urged that the process is secondary to destruction of the tubules. In these cases the epithelium presents an altered condition, while the interstitium is established.

STRAUS and GERMONT, in France, studied the effect of ligation of the ureter. They did not, however, find any interstitial process. They are inclined to attribute the absence of antiseptic precautions observed in their experiments. If such precautions are not observed, micro-organisms may find entrance; and through these, directly interstitial process may be produced. This, however, be allowed much weight. It is an assumption to suppose that micro-organisms producing such effects and no others, and quackery as a means of explaining a discrepancy between the results obtained by two sets of experimenters. The results of the experiments of AUFRECHT have, moreover, confirmed AUFRECHT's views on the mode of origin of tube-casts by the process of the epithelium of separate clear spherules, and within the tubules. They have also confirmed the view of the adventitia and muscular coat of the small arteries and the thickening of the membrane propria.

But the evidence which AUFRECHT has adduced that in one form of diffuse nephritis the morbid process commences within the tubules cannot be regarded as necessarily applicable to all forms of renal inflammation. Experimental evidence is needed regarding the process in other forms of nephritis, which proceed to a greater degree of structural change than that which follows the transection of the ureter. Some further evidence AUFRECHT is now in a position to supply. In a communication to *Centralblatt für die Med. Wissenschaften*, in which he reviews the facts above alluded to, he states that by the subcutaneous injection of small quantities of cantharidin, suspended in oil, he has succeeded in producing almost all forms of nephritis—the so-called acute parenchymatous form, the diffuse parenchymatous-interstitial form, and even the contracted kidney, with granular surface and marked degenerations. All these varieties of nephritis were produced by the

the method, the only difference being that to give rise to contracted kidney the injections of cantharidin had to be frequent. As a rule, the largest and strongest animals required the greatest number of injections; but in one case, a single injection in a rabbit which had just completed a period of lactation set up an acute parenchymatous nephritis, which was fatal. This interesting pharmacological fact has afforded AUFRECHT the opportunity of studying the evolution of these morbid states. In the earliest stage the glomerular epithelium was found to present considerable swelling, and was separated from the wall of the capsula. The tubular epithelium was cloudy, swollen, and contained clear refracting bodies, which, becoming free, produced tube-casts, just as in the case of ligature of the ureters. Subsequently the epithelium of the glomeruli became swollen, as well as the nuclei of their vessels. That these changes are really inflammatory is shown by the appearances presented in a later stage, when it deserves the name of "parenchymatous-interstitial nephritis." The changes in the epithelium of the convoluted tubules were manifested in a still more considerable degree. The cells were small, flat, and pale, and were nowhere absent, though some of the glomerular epithelium had disappeared. The vessels contained little blood, as if the swelling of the nuclei had prevented the passage of the blood into them. The interstitial tissue was, however, increased in area in all parts, in consequence of swelling of the nuclei, especially between the convoluted tubules and in the neighbourhood of the glomeruli. There was no indication of an excess in the number of cellular elements in the interstitial tissue, or of any migration from the vessels. From these facts AUFRECHT concludes that the changes must be ascribed to a specific affinity of the cantharidin to the epithelium, exciting in the latter some chemical process, which ultimately influences also the interstitial tissue in the way described.

Granular degeneration of the kidney, in its most perfect form, was produced by twenty-five injections of cantharidin (0.025 gramme), extending over four months. The microscopical appearance of the organ was similar to that of the same condition in man. By the contraction of the interstitial tissue the glomeruli and renal tubules were much narrowed. The former were denuded of their epithelium, and their structural elements could scarcely be recognised. The epithelium of the renal tubules was shrunken, and the bodies of the cells had a protoplasmic aspect. Here and there the lumen of the tubules was occupied by casts. These results AUFRECHT holds to be evidence of the etiological and pathogenetic relation between parenchymatous nephritis and the contracted kidney, and that even in the latter the morbid process begins within the tubules.

THE letters of Professors GAIRDNER and STRUTHERS in THE LANCET of last week, and the letter of Dr. GLOVER which we publish to-day, show how curiously different is the view of the same subject taken by persons who must have one feeling in common—a wish to maintain the fame of the Scotch universities and the value of their degrees. Perhaps, in the face of an actual Bill before Parliament introduced by a powerful Government, these differences will grow less. The tone of Dr. GAIRDNER'S letter justifies this hope. He admits the care and consideration given to the

subject by the Royal Commission, and has no doubt that the universities will consider such a Bill "with every desire to aid in the settlement of a long-voiced question." He speaks of the educational interests with which the Scotch universities are charged, and compares these with those of the London schools. Dr. GAIRDNER will scarcely deny that, if Scotch universities are doing the work of English schools in such a vital matter as that of medical education, they should be prepared to submit to the public tests to be applied to English medical schools, and, for that matter, to English universities, which do not come into competition with medical schools, as the Scotch universities, to their credit, do. The Scotch universities are no longer merely Scotch institutions. They educate and examine probably half the practitioners of the empire. It is a very small thing to ask them to submit to imperial tests at a cost of five pounds.

Dr. STRUTHERS' view of this subject throughout has been very local. The whole demand for legislation originates, according to Dr. STRUTHERS, in the jealousy of London corporations. The whole cure for existing scandals and evils is for the London corporations to combine as the Scotch corporations have done, and to prohibit, if necessary by law, registration of incomplete qualifications. Dr. STRUTHERS sees no temptation in the circumstances and work of the Scotch universities to be guarded against. They are perfection, and scarcely elsewhere is any proper education to be had. He astonished Professor HUXLEY by denying that as good education in anatomy and physiology is to be got in London as in Scotland. But the most astonishing part of Dr. STRUTHERS' views is his entire complacency with the examinations of the Scotch corporations. To him it seems nothing that visitors of the Medical Council and most authoritative witnesses before the Royal Commissioners have seriously disparaged these examinations, and that the Commissioners have given prominence in their Report to the fact of such damaging testimony. With complete and happy disregard of this slight circumstance, he is never tired of telling us that all the English bodies have to do is to imitate the Scotch ones. Holders of Scotch diplomas have a right to expect more serious treatment of the evidence that has so damaged the reputation of their licence to practise, and he is no friend to Scotch corporations who does not try hard to improve a system that provokes such disparagement.

AT the ordinary meeting of the Manchester Medical-Ethical Association, held on the 8th inst., it was unanimously resolved, at the instance of Dr. IRWIN, that "the medical and sanitary departments of our mercantile marine are in a highly unsatisfactory condition, by which the lives of passengers are frequently endangered." It was further resolved "to press upon the Government the necessity of immediate inquiry into the position, status, and efficiency of surgeons upon passenger ships." There can be little doubt that the time has arrived when the whole question of the regulations, remuneration, and duties of ship-surgeons, especially upon Atlantic steamers, should be reconsidered and revised. The surgeon is usually relegated to one of the worst cabins in the whole vessel, and which is frequently inferior to that allotted to the third and fourth officers. A recent inspection of the quarters allotted to ship-surgeons upon the

leading Atlantic Ocean steamers has revealed the fact that, as a rule, the surgeon is placed in an inner cabin close to the engines, and of very inadequate proportions. Here he is frequently surrounded by his medicines and other impedimenta, and a couch, which must also be used for professional purposes, is all the sleeping accommodation provided. Owing to want of light, it is impossible for anyone to diagnose successfully any case, much less a case of eruptive fever or obscure disease. The Board of Trade official, with satanic irony, when signing the ship-surgeon's warrant of appointment, exhorts him to do as much scientific work as possible during the voyage, and to keep accurate records of all the cases which come under his care. Having issued these instructions, he carefully abstains from visiting the surgeon's quarters, on the principle, it is believed, that "where ignorance is bliss, 'tis folly to be wise." The ship-surgeon's pay, from £5 to £10 per month, is ridiculously small when the work he has to do and the responsibility placed upon him are considered. He occupies a position which should be second in importance only to that of the captain, and he is remunerated at the same rate as the cook, steerage-steward and fifth engineer. He is supplied with no assistant, no dispenser, no nurse, no servant, and therefore in times of general sickness his duties are far too great for any one person to perform satisfactorily. Ship-surgeons at the present time have no control over the ventilation of the vessel or its hygiene, such matters being left to chance or the benevolence of the captains. In view of these facts it can be in no way surprising that there should be an excessive mortality among passengers—"a far higher mortality than is justified by the necessities of transit." From recent reports we learn that the death-rate among the passengers of all European vessels entering New York during the ten years ending December, 1880, was 44.6 per 1000 per annum; while of 315,850 persons who embarked on English ships for North America during 1881, 185 died in transit. We have not space to enumerate the many abuses at present existing upon Atlantic Ocean steamers, but we have said enough to prove that the resolutions adopted by the Manchester Medical-Ethical Association are well timed, and that the Government must be induced to institute an inquiry forthwith. We would suggest that one of the London Societies should initiate a discussion and organise a deputation, with the view of securing the necessary legislation without further delay.

### Annotations.

"Ne quid nimis."

#### BACHELOR OF SURGERY AT CAMBRIDGE.

THE first examination for this degree, which has been instituted by the new statutes of the University, took place last week. Of the four candidates who presented themselves three were approved—viz., Morris of Caius College, Pitt of Clare College, and Sheild of Downing College. The Examiners were Mr. Holden and Mr. Bryant, both members of the Court of Examiners of the College of Surgeons. The examination consisted in operations on the dead body, which were done at the anatomical school; and the application of surgical apparatus and the examination of patients, which took place in Addenbrooke's Hospital. Before admission

to this examination candidates must have passed nine terms in the University examination in Civil Surgery. The first and second parts of the third examination are the Principles and Practice of Surgery, and the degree of the candidate or second part of the third examination is the graduate in surgery. The examination for Bachelor of Medicine in Practical Surgery, including the degree of Bachelor of Medicine, is held in addition. It is clear that the examination men, will take a high standard. There is also a still higher examination for Master in Surgery, which is held every year, and for which new

#### UNCERTIFIED DEATHS.

THERE are few of the facts which Dr. Tatham's recently published report on Salford during 1881, which shows the relation between the causes of death and the recorded deaths, that are so recorded within that 1 certified deaths in Salford against 2.4 per cent., the large English towns described in the Weekly Return. The number in Salford last year was in Hull and Oldham; upon the proportion of the previous year. Dr. Tatham's connexion with this excessive mortality to the fact that the proportion was abnormally low in Hull, and Salford. The year in the twenty English towns, whereas it was only 2.8 in Salford. Dr. Tatham does not mention the facts of the high proportion of uncertified deaths, the attendance of a registrar, exceptionally small proportion to Salford, Dr. Tatham's report in Birmingham, in which the number in 1881 did not exceed 2 inquest cases were as he could have wished that the causes of the large number in Salford: whether it is due to unqualified and irregular practitioners, or to neglect of attendance. There is little of all or any of these causes, an increase in the number

#### THE RECENT

THE statement circulated that sentries had been frozen at Curragh Camp, is, we believe, devoid of truth, however, unfortunately. During such exceptional weather, visited the northern ports, some precautions, such as duty, or sending two po-

ads, should be adopted in the interests of these hardened and responsible servants of society. Comedy, however, has alternated with tragedy, and the spectacle of the Nottingham County Court judge, whilst administering justice, sitting enveloped in rugs, and being addressed by masters and solicitors wearing great-coats and mufflers, is the grotesqueness of which is only foiled by the fact that recent death of a promising young solicitor is attributed to cold caught in that Court, the ventilation and warming of which are in a most unsatisfactory state.

#### REGINA v. TAYLOR.

THE conviction of Louisa Jane Taylor, aged thirty-six, at the Central Criminal Court (before Mr. Justice Stephen) of the murder of Mary Ann Tregillis with sugar of lead is of sufficient rarity and importance to be recorded. The deceased was eighty-one years of age, and lived with her husband, a naval pensioner, aged eighty-five, at Plumstead, near Woolwich. Early in August, 1881, the prisoner came to live with Mrs. Tregillis, and slept in the same room with the deceased. After this Mrs. Tregillis fell ill. She complained of being weak, and that "her throat burnt like a hot coal." She only complained of pain when medicine was given her (by the son), and was more sick at night than in the daytime. About a fortnight before deceased died it was noticed, both by her husband and a neighbour, that her teeth had turned black. On Oct. 1st deceased had an attack of convulsions, and one or two attacks subsequently. She also had tremor of the hands. She lost her speech on Oct. 20th, and died on the 23rd. It was proved that between August and the death of deceased's death the prisoner had on three several occasions purchased an ounce of sugar of lead. The deceased, in a "dying declaration," had asserted that the prisoner was in the habit of mixing a white powder with the medicine which the doctor ordered for her, and that it was after taking medicine thus treated that her sufferings increased. The medical evidence went to show that deceased became ill on or about August 23rd with sickness, shiverings, perspiration, and abdominal tenderness. Her skin was sallow, her teeth black, and there developed a characteristic blue line on the gums. Seventeen days before deceased died the prisoner ceased to attend upon her, and a few days before death the deceased had an ordinary hemiplegic attack, which it was not alleged was due to lead poisoning. Dr. Stevenson on analysis found distinct evidence of lead in the liver, spleen, kidneys, stomach, and brain. The drinking water of the house contained no lead. No mention was made in the evidence of the coarse sensations (if any) which produced the hemiplegia. The motive alleged for the crime was the desire on the part of the prisoner to succeed the deceased as the wife of Tregillis, and thus enjoy with him (aged eighty-five) the pension of £40 a year which he is receiving from the Admiralty. The defence was that the lead had been administered by the husband and not by the prisoner, and the prisoner's possession of the lead was accounted for by the alleged necessity which she had of using a vaginal injection made of lead. The defence was a flimsy one, and there can be no doubt that Taylor attempted to compass the life of old Mrs. Tregillis. What was the actual cause of death is not so certain. The deceased was eighty-one, she had an attack of hemiplegia shortly before death, and she had not had any poison administered to her for seventeen days previous to her decease. Cases of death from sugar of lead are rare; cases of criminal poisoning with this agent are infinitely so. The fatal dose in cases of acute poisoning can hardly be said to be known. Some have suffered only slightly after an ounce, and several cases of recovery after this dose are on record. There were no signs of corrosion or irritation post mortem, and almost the only symptoms of chronic lead

poisoning at the time of death was the blue line on the gums. The very marked blackening of the teeth which was noticed by those in attendance on Mrs. Tregillis may, no doubt, be accounted for on the supposition that she never cleaned her teeth, and that they became coated with lead sulphide; but nevertheless it is not among the ordinary symptoms of lead poisoning. The blue line round the edges of dirty teeth is due to the deposition of lead sulphide in the tissue of the gums. That Taylor is a heartless creature and richly merits punishment, there can be no doubt. That lead poisoning was the cause of Mrs. Tregillis's death is not so certain. Old Mrs. Tregillis's death was probably hastened by the administration of the lead, but this is more a probability than a proved fact.

#### THE HARVESTING OF ICE.

THE season has again come round when large quantities of ice are collected and stored with a view to its being used during the summer months in connexion with our food supplies. Some of it is actually mixed with foods and drinks, more still is brought into close contact with such articles of diet as fish, poultry, butcher's-meat, &c., in order that it may act as a preservative. Unfortunately, however, but little regard is had to the sources whence the supply is derived, and after every frost, carts laden with ice which has been collected from the surface of ponds, canals, and streams which would be studiously avoided as water-supplies, may be seen passing along our streets to the shops of tradesmen dealing in articles of food and drink. That the use of such ice for the purposes to which it is put is not without risk has been shown both in this country and more especially in America, where in the warm weather ice enters largely into the list of table requisites; indeed, it has been further proved that ice has acted as the vehicle of disease germs capable of conveying enteric and scarlet fever, and its use has also been associated with conditions of ill-health which have much resembled these and other specific fevers. The carelessness which has obtained in selecting sources for the collection and storage of ice has been largely due to the fact that there is a very general opinion that in the act of crystallisation water practically rids itself of all its injurious qualities, however offensive it may be in its liquid state, and acting on this view, it is notorious that ice for domestic use has been, and still is, collected from streams receiving sewage, ponds that are offensive in summer time with decomposing vegetable growth, and similar sources. There is also a sufficient amount of truth in the general opinion as to the process by which noxious and foreign matters are eliminated from water during the act of freezing to lead to some lack of caution on the part of the uneducated, but recent experience has clearly shown that the process of purification is only a partial one. In connexion with this subject an interesting paper comes to us from across the Atlantic in Dr. Wight's First Annual Report to the Board of Health of Detroit, and it includes a copious reference to certain recent experiments by Mr. C. P. Pengra, an analytical chemist. In the first instance, urea, as a representative of the crystalloids, was mingled with water, which was then frozen; and it was found that whereas 100 cubic centimetres contained 0.83 gramme before freezing, they still retained 0.50 gramme when in the form of ice. Very similar results followed in experiments made with urea as found in urine, and with other substances, such as grape sugar. The next experiment was with the colloids; albumen, both from the egg and from a case of albuminuria, being taken as a sample, and it was shown that the amount retained in the frozen mass was greatest at its under, and least at its upper, surface. Thus 50 cubic centimetres from the lower third contained 6.87 grammes, the same quantity from the middle and upper thirds containing 4.19 grammes and 3.0 grammes

respectively. Other experiments with the same material showed that the purification which did take place amounted to about 20 per cent. of the total admixture. The results would doubtless vary according to such circumstances as the rapidity of freezing, but since in all the instances recorded the specimens were frozen naturally, they amply suffice to show, as the author contends, that pure ice can only be procured from water free from impurities, and that ice for domestic purposes should never be collected from ponds or streams which contain animal or vegetable refuse or stagnant and muddy contents.

#### FLOORING AS A MEDIUM OF INFECTION.

THE *Zeitschrift für Biologie* lately published a statement on the above subject from the pen of Dr. Emmerich of Leipsic, in which it is remarked that notwithstanding the attention paid to disinfecting walls, furniture, bedding, and clothing after illness of an infectious character has taken place in a house, the danger from the flooring, though usually neglected, is no less real than that which might arise from any of the sources enumerated. The material used in filling up flooring is often of a nature, it is urged, capable of itself producing, under certain circumstances, emanations of a noxious character. Should, however, even quite harmless materials have been used for the purpose indicated, it is argued that while a house is inhabited there is a gradual accumulation of organic substances going on which penetrate through the openings in the flooring. The constant washing tends, it is said, to make the filling damp, and in addition to this source of danger the temperature under the flooring is often higher than that of the room itself, it having been demonstrated that when the temperature of a room has been 61° Fahr., that of the space underneath the boards has been as high as 90°. This has apparently been specially the case in the vicinity of a stove. This fact is referred to in connexion with the theory held by Dr. Koch that a temperature of 90° is necessary for the development of bacilli, the existence of which he has demonstrated. This temperature as a normal one was found by him not to exist in connexion with our daily surroundings. In addition to dry-rot, which is not without an influence on health, Dr. Emmerich found in numerous samples of the filling used underneath flooring quantities of bacteria. That other substances of a noxious character were present was likewise proved by the fact that Dr. Emmerich and his assistant became ill whenever they had been engaged in protracted investigations of this kind. It is evident that if infection lurks in the flooring, the most thorough measures of disinfection which may be taken as regards other portions of a room may fail to restrain the spread of disease. This explains how illness has been found to originate in one room of a house, or even in certain portions of a room. A mouldy smell in a room after it has been washed is said to be in some measure an indication of the existence of the state of things which has been described. It is, however, remarked that the absence of such a smell must not be taken as conclusive proof of the room being free from any such noxious influences from underneath, as earth has the property of checking the bad odour of decaying organic matter without, however, arresting the process of decomposition. The practical recommendations of Dr. Emmerich consist for the most part of suggestions for the prohibition of the employment as filling material in new buildings of any substance containing phosphorus, potash, or magnesia; it being remarked incidentally that they are notably abundant in coal-slag. For houses already inhabited, he recommends that the inner portions of the flooring should be shut off by an air-tight and water-tight substance from any communication with the air of the room itself. It is further suggested that divisions between the boards should

be avoided as much as possible should be coated with in order to render them moisture.

#### APPOINTMENTS

WE are glad to record Jacob as medical officer Sanitary District. In the has held this appointment attaching to his office with of comparative healthiness pressed on sanitary measures improvement in the health any special incidence of disease been indefatigable in tract ports, both as to such or sanitary circumstances as such as to command confidence he has recommended. The paper of the county, em testimony. Owing to the recently been converted pointment to this parish but we hope that no effort place from the united district up to the present. Both glad to note a recommendation Board to the effect that not successfully served their comparatively long terms. bined district the recommendation years, and though the authority it for six years, yet the principle the office of a health officer one which we are glad to see have found themselves serve that at frequently recurring be compelled to submit to not only prevented the course of improvement in many competent men from joining The step taken is one in bably the first instalment of the central authority of the of health.

#### THE REFUSAL OF

THE iniquity—we can see the “workhouse test” is in this rich nation. If we see one of the devices by which us rather say by which police school are dragging this social confusion and consequence test is an offence against worthy of men with brains anything be more unnatural married folk struggling against unless they will go into torn asunder at the moment wane, and when the only the fag end of a luckless effort in hand. It is hard to write is smirched over with the this device. We have seen our veins of the encouragement has been held up to reproving.” Let us tell those phrase in the face of Engl

instincts of our nature. The cold calculating spirit sits down to tottle up its figures to prove that beggars encouraged by giving them alms, has found its fruition in the "workhouse test." There is no humanity, no true philanthropy, underlying this crazy cleverness. Give to the poor!—on their heads be it, not on ours, if charity is abused. The struggling creatures who are striving to keep out of the "house," who do not wish to be wholly dependent, who have a scrap of self-respect still left in them, be helped to it, not left to die. We appeal to the ratepayers of this country to say, when next the election of guardians occurs, that not one man shall be returned who will refuse out-door relief to the poor. Make the relieving officers and the overseers do their work, and see to it that the public money is not wasted on impostors; but let it once for all be understood that the ratepayers of England will not permit the funds to be subscribed for Poor-law purposes to be so administered that the black crime of letting honest and true-hearted people die because they will not be separated lies at their door.

### FACE POWDERS.

It is necessary to raise a warning cry against a most mischievous statement which has recently been circulated, and which has already done harm, to the effect that "arsenic in small doses is good for the complexion." It is not difficult to imagine the risks women will incur to prevent or improve their "good looks." No more ingenious device for recommending a drug can be hit upon than that which the authors of this most baneful prescription "arsenic for the complexion" have adopted. Suffice it to recall the fact that for many years past chemists and sanitarians have been labouring to discover means of eliminating the arsenical salts from the colouring matter of all-papers, and certain dyes once largely used for certain classes of clothing. It is most unfortunate that this hopelessly antagonistic recommendation of arsenic to improve the complexion should have found its way into print. Those who employ the drug as advised—and there are many either ready using it or contemplating the rash act—will do so at their peril. So far as they are able, however, it will be a duty of medical men to warn the public against this pernicious practice, which is only too likely to be carried on secretly. It is not without reason that we speak thus indignantly, and urge practitioners to be on the *qui vive* in anomalous or obscure cases.

### "NOTIFICATION" IN SCOTLAND.

PRESENT appearances would indicate the probability that the question of notification of infectious diseases, its value as a sanitary agent, and the proper persons on whom to lay the responsibility, may be fought out during next session in connexion with the proposed General Police Bill for Scotland, to be introduced by the Lord Advocate on the part of the Government. This Bill will be applicable to all the large towns and to police burghs, so that practically the whole urban population of Scotland will fall within its scope. Considering the adoption of the principle in local Acts by the authorities of Edinburgh, Dundee, Aberdeen, and Greenock, the incorporation of similar clauses in the now unnecessary private Bill for Glasgow, the strongly expressed opinion by the medical officers of health consulted by the Board of Supervision, and the evident bias of that Board itself, there need be little doubt that a clause requiring compulsory notification will form part of the measure of next session. Wherever professional opinion has been consulted, determined opposition has been shown to the proposal to make the medical attendant directly responsible for this information; but unless concerted and vigorous

action be arranged for, emphatic opinion will go for little when the question comes before Parliament. So far as Scotland is concerned it is remarkable that the only town where a large reduction in zymotic mortality has taken place subsequent to the operation of compulsory powers is Greenock, where the intimation is given by the householder. Still more curiously, there is no medical officer so eager in his anxiety to burden his fellow practitioners with this obnoxious work as the officer of the very town where such direct good has resulted from another system. Dr. Littlejohn has all along favoured the system which has worked with little friction, but the Edinburgh medical men and their patients are probably little troubled with undue interference, as they have themselves to say whether any attention by the authorities is or is not necessary. The foot-note in which the medical attendant is allowed this liberty, and which must have saved a world of trouble to the authorities, is objected to by some men who can only view the world and its doings through the spectacles of a medical officer of health. The Scotch authorities at present enjoy the counsel of some such men, and if their advice against all compromise be taken, it will behove the profession, not only throughout Scotland, but by all its powerful combinations throughout the country, to take such measures as will make its voice effectually heard on this important question.

### AN ENGINEER'S LUGGAGE.

THE almost motherly care exercised by the Government, and others in authority over us, respecting our lives and welfare, which is so often held up to ridicule, is fully justified if we may judge by one instance of the extreme recklessness and utter disregard of human life and property displayed by some members of the community. An engineer, of Newcastle-on-Tyne, was on the 15th inst. fined £20—a most inadequate penalty—for carrying, in conjunction with his assistant, a large quantity of blasting gelatine, which was to be used to blow up a dangerous wreck at Deal, in a second-class smoking carriage on the North-Eastern Railway. The explosive compound was carried in hand-bags, and it is painful to imagine the probable result of an accidental kick by a blundering passenger, or, supposing these bags to have been placed on the network above the seats, a sudden jerk of the train in starting or stopping which might have sufficed to dislodge them. A glowing fusee or the smouldering end of a cigar might have fired a charge that would have annihilated passengers and train, and would have effected in a moment such widespread destruction as fogs, deficiency in the working of signals and block system, or any of the numerous causes which usually contribute to our railway catastrophes, would not bring about in a decade.

### A HEAVY BRAIN.

IT is well known that, although many distinguished men have had very large brains, these have been occasionally equalled by the brains of persons who never displayed remarkable intellect. Another illustration of this has been lately published in the *Cincinnati Lancet* by Dr. Halderman of Columbus. A mulatto named Washington Napper, aged forty-five years, recently died in the hospital at that town in consequence of purulent infection due to an abscess of the thigh. His brain was found to weigh 68½ oz., nearly 5 oz. more than the famous brain of Cuvier. His height was six feet, his limbs are said to have been ape-like in length, his head was massive, lips thick, lower jaw prominent, but his forehead large and well developed. He had been a slave until the year 1862, and had never been regarded as particularly intelligent; he was illiterate, but is said to have been reserved, meditative, and economical.

## THE METROPOLITAN ASYLUMS BOARD.

THE Metropolitan Asylums Board seem doomed to disappointment in their relations with the central authority. Having expressed themselves as willing to undertake any or all of the duties recommended by the Royal Hospital Commission they appealed to the Local Government Board and asked to be informed of the intentions of that board with respect to the Commissioners' Report. It was hardly to have been expected that in answer to such a communication the Government would have divulged all its intentions with regard to future legislation in the matter of dealing with infectious diseases in the metropolis; but having regard to the arduous and unaided labours of the Asylums Board in the past, and to their offer to work in the future, the central authority might surely have done something more than again tender them their sympathy and say they could give them no information at all. As Sir E. Hay Currie stated, the managers could not but feel that such an answer indicated, on the part of the Local Government Board, a want of interest in the serious troubles to which they had been exposed in the performance of their duties.

## MR. FAWCETT.

WE are glad to learn that Mr. Fawcett has made considerable progress since our last notice of his case. He has had an attack of rheumatism and some aphthous inflammation of the mouth, which, as well as the other complications in the case, have now nearly subsided. There remain only some temporary weakness of the action of the heart, a slight rise of temperature at night, and inability to sleep, but these are not unusual results of a severe attack of fever such as Mr. Fawcett has undergone; and, having regard to the possibility of further complications in the course of convalescence, there is nevertheless good reason to anticipate a favourable and complete recovery.

## THE REPRESENTATION OF FINSBURY.

THE rumour which has been circulated respecting Dr. Richardson's candidature for Finsbury, rests, we learn, on the following grounds:—At present there is no vacancy in Finsbury, and Dr. Richardson himself has taken no initiative whatever as to any future vacancy; but certain of the sections of the Liberal party of the borough have applied to him to ask if he would stand in the event of a seat becoming vacant, or in the event of a general election. To this he has replied, that on the condition that he is not rendered liable for expense of any kind connected with the election, he will respond to the request, and it is pretty generally known that with this proviso plainly understood, he has recently, on invitation, met the members of the committee of the Liberal Association and has had a long deliberation with them. His candidature has also been incidentally referred to at several public meetings in the borough, and has been enthusiastically received.

## NAVAL GOOD-SERVICE PENSION.

WE hear of dissatisfaction with the late award of the good-service pension of £100 a year, vacant by the death of Inspector-General Dr. J. W. Johnston, R.N., being made to Inspector-General Dr. H. J. Domville, C.B., notwithstanding the very high claims of three of his seniors of the same rank, of whom one is a C.B., wounded in action under the forts of Sebastopol, and another a K.C.B., in recognition of their meritorious services. We would not assume to be arbiters in such questions, while we find it difficult to assign, as some have done, occult motives for an award which is so obviously prejudicial to Dr. Domville's senior officers.

A CONSIDERABLE preval in Salford, and pending f has advised that the mill that all using milk should near Manchester, there is a disease. Reports as to it tary authority both by the Dr. Henry Tomkins of M having received special in yet the disease has attacked houses. The water and th

in no way implicated, but in the area specially affected defective and blocked sewer had recently been opened, to this the outbreak is provisionally attributed. Further reports as to both these epidemics are promised.

AN alarm of fire was raised in Glasgow Royal Infirmary Monday evening. A chimney formed of iron tubing, which passed through the roof of a small outshot building, caught fire, and burned so fiercely that for a short time the structure seemed in some danger. Through the exertions only of the superintendent and the resident assistants the fire was prevented from spreading further. In view of the terrible results which would certainly ensue from the occurrence of a fire in such an institution, it is to be hoped that the Royal Infirmary authorities have their fire extinguishing apparatus in proper order, and judiciously placed about the buildings. The new part of the Infirmary is well supplied with hose, &c.; but what of the "old house"?

AN order was lately made by a Justice of the Peace for Norfolk for the vaccination of a child whose father had been told nine years before for refusing to have it vaccinated. Putting the power of the Magistrate to make the order, counsel on behalf of the father made an application to the Queen's Bench Division to raise the issue before the Court, but permission to do this was refused, Mr. Justice Hawkins deciding that to do what was asked would only be to raise doubts about what was perfectly clear.

THE French doctors in Nice are, it appears, up in arms against their English and other foreign brethren established there that favoured health resort. A general meeting of the medical body has been held, at which protests were entered against the manner in which alien practitioners monopolise the most lucrative practice. Amongst other points urged it was stated that many of the intruders are not qualified medical physicians, and consequently have no right to practise anywhere in France.

MR. PRIDGIN TEALE, in a letter to the *Leeds Mercury*, calls attention to a rough-and-ready method of filth disposal adopted in the town. "Within the last few months," says Mr. Teale, "hundreds of cartloads of ashpit refuse and 'night soil' have been tipped into an old quarry by our corporation carts," with what effect upon the health and comfort of the immediate residents may be safely left to the imagination to depict.

ANTISEPTICISM grows in favour in Italy, if we are to judge from an article "On the Foundations of Modern Surgery," first published by Professor Andrea Ceccherelli in the *Rivista degli Ospitali* (Milan, Dec. 13th). The author is a firm believer in the clinical potency of micro-organisms, and extols antiseptic dressings as amongst the greatest of modern surgical conquests.

It was decided at a meeting held at Liverpool on the 15th inst., the Mayor presiding, to erect at a cost of £100,000 a new and more commodious infirmary, the present one being quite unsuited to the present requirements, and the sanitary arrangements also being defective. Subscriptions to the amount of £50,000 are already promised.

THE expedient of pouring oil upon the broken waves of the ocean to produce a comparative calm is, curiously enough, spoken of by some of the scientific journals as a new thing. The fact is that this action of oil in stilling breakers is as old at least as Aristotle.

DR. MEREDITH, in the *Birmingham Medical Review*, recommends oil of peppermint as an external application for allaying the neuralgic pain so often complained of in cases of herpes zoster (shingles).

DR. D. G. F. MACDONALD has in the press a work on "Grouse Disease, its Causes and Remedies," with illustrations by Elwes. It will be published by Messrs. W. H. Allen and Co. early next month.

## Public Health and Poor Law.

### LOCAL GOVERNMENT DEPARTMENT.

#### REPORTS OF MEDICAL OFFICERS OF HEALTH.

*St. George's, Hanover square.*—According to Dr. Corfield's annual report the death-rate for this parish is still maintained at a low ebb, it being 16.9 per 1000, as opposed to an average, during the ten preceding years, of 17.9. The population is all but stationary; for although there has been an increase in the neighbourhood of Mayfair, there has been a still greater decrease about Hanover-square, the result being that in 1881 there were 185 less inhabitants than in 1871. The mortality under one year of age is 13.4 for every 100 births. This rate is low, but the circumstances of the district are exceptionally favourable to the majority of the children born. The mean duration of life in the parish is also high. During the past seven years it has been 50 years; last year it was 50.2 years; whereas it is but little over 35 years for London generally. Apart from deaths of non-parishioners in St. George's Hospital, no special prevalence of infectious disease is indicated; but having regard to the amount of sanitary work done, such a result must in part be attributed to the careful action taken against the spread of infection and against the continuance of conditions unfavourable to health. Amongst other items we notice that inspection of 236 houses in which infectious disease had prevailed had been carried out, and that over 3000 large articles, in addition to many smaller ones, had been dealt with in the hot-air disinfecting stove. The stove is that designed by Dr. Ransom, F.R.S., and it is reported to work satisfactorily in every respect.

*Bethnal-green; Sewer Ventilation.*—According to Dr. Bate's annual report for the parish of St. Matthew, Bethnal-green, the district had in the middle of 1881 a population of 127,180, the number of houses being at the rate of one to every 7.2 inhabitants. The death-rate amounted to 24.0 per 1000, this rate exhibiting a slight increase on the average for the ten preceding years. The birth-rate was high, amounting to 41.1 per 1000, but the infantile mortality was also high; the rate of death amongst infants under one year reaching 15.3 per cent. of the births registered. Small-pox attacked 737 persons, of whom 680 were removed to hospital. Owing to the rapid filling of the Asylums Board Hospitals the vestry provided additional hospital accommodation at Plaistow, and Dr. Bate remarks that in no single instance was it necessary to resort to compulsory measures in order to get the cases removed. Measles was very fatal during the year, and it is to be regretted that sanitary interference can as yet do but little to prevent its spread and fatality, for owing to the fact that it is so highly contagious before it can be diagnosed, even isolation is rarely of any avail. Unfortunately, however, Bethnal-green is not yet provided with all the means which are proved to be of use in preventing the spread of infectious diseases. In 1880 Dr. Bate prepared an exhaustive report on the value of the different disinfecting chambers, and concluded by recommending the erection of a Washington Lyon's steam apparatus. Nothing has, however, been done in the matter; and hence when cleansing and disinfection of premises, as also the burning of beds, &c., have been carried out in houses where infectious disease has prevailed, the disease breaks out again by reason of the use of infected clothing.

A separate report is issued by Dr. Bate on the question of the ventilation of the sewers in his district. He would, as a general rule, advocate a system by which ventilating shafts should be carried from the sewers to a height above the level of house chimneys, some of the openings being fitted with cowls so as to ensure a down current of fresh air. The

sk since the middle of May last. During the first eleven  
 aks of the current quarter the death-rate in the city  
 raged 25·2 per 1000, against 21·2 in London and 20·1  
 Edinburgh. The 224 deaths in Dublin last week showed  
 increase of no less than 58 upon the number in the pre-  
 us week, and included 20 which were referred to the  
 acipal zymotic diseases, against 14 and 12 in the two  
 ceding weeks. These 20 deaths included 9 which were  
 ributed to whooping-cough, 8 to "fever" (typhus, enteric,  
 1 simple), 2 to diarrhoea, 1 to diphtheria, and not one  
 ner to small-pox, measles, or scarlet fever. The death-rate  
 m these zymotic diseases was equal to 3·0 per 1000 in the  
 y, while the rate from the same diseases last week was  
 in London and 3·6 in Edinburgh. The fatal cases of  
 ooping-cough in Dublin, which had been 5 and 2 in the  
 o previous weeks, rose to 9 last week, while the 8 deaths  
 erred to "fever" were within one of the number in the  
 vious week, and were equal to a rate more than twice as  
 gh as the average rate from this cause in the twenty-eight  
 ighish towns. The deaths of infants showed a marked  
 rther increase upon recent weekly numbers, and those of  
 lerly persons were also more numerous.

### THE SERVICES.

THE Greenwich Hospital pension of £50 a year, vacant by  
 e death of Retired Deputy Inspector-General of Hospitals  
 d Fleets Alexander Cross on Dec. 3rd, has been awarded  
 Retired Deputy Inspector-General of Hospitals and Fleets  
 ndrew Murray from that date.

ARMY MEDICAL DEPARTMENT. — Brigade Surgeon  
 nderick M. Skues is granted retired pay, with the  
 onorary rank of Deputy Surgeon-General. Brigade  
 rgeon Sir Robert William Jackson, C.B., is granted  
 tired pay, with the honorary rank of Deputy Surgeon-  
 eneral. Surgeon John Percival Hunt, M.D., from half-  
 y, to be Surgeon, vice D. O'Sullivan, who has resigned  
 s commission.

MILITIA MEDICAL DEPARTMENT. — Surgeon-Major George  
 ilson, Royal Monmouthshire Engineer Militia, resigns his  
 mission; also is permitted to retain his rank, and to  
 ear the prescribed uniform on his retirement.

ARTILLERY VOLUNTEERS. — 1st Sussex: Surgeon Heckstall  
 uth resigns his commission; also is permitted to retain  
 s rank, and to continue to wear the uniform of the corps  
 s his retirement. 1st Kent: Acting Surgeon William  
 yre Blennerhassett Atthill resigns his appointment.

RIFLE VOLUNTEERS. — 1st Ayrshire: William Sneddon,  
 ent., M.D., to be Acting Surgeon. 9th Lanarkshire:  
 cting Surgeon James McIlade resigns his appointment.  
 t Lincolnshire: Honorary Assistant Surgeon George  
 alker resigns his commission. 14th Lancashire: Surgeon  
 nderick Blakesley Mallett, M.D., is granted the honorary  
 ank of Surgeon-Major. 1st Midlothian (Leith): James  
 allan Gray, Gent., to be Acting Surgeon. 22nd Middlesex  
 entral London Rangers): John Robert Kemp, Gent., to  
 e Acting Surgeon. 6th West Riding of Yorkshire: John  
 utcliffe, Gent., to be Acting Surgeon. 2nd East Yorkshire:  
 D. Ridpath, M.D., to be Acting Surgeon.

ADMIRALTY. — Fleet Surgeon George William John  
 utherland having been placed on the Retired List from  
 Nov. 20th last, has been allowed to assume the rank and  
 title of Deputy Inspector-General of Hospitals and Fleets  
 on the Retired List from that date. In accordance with the  
 provisions of Her Majesty's Order in Council of April 1st,  
 1881, Staff Surgeon Thomas Harvey has been placed on the  
 Retired List of his rank from the 8th instant.

The following appointments have been made: — Staff  
 Surgeon Evelyn R. H. Pollard, to the *Albatross*; Surgeons  
 Archibald M'Kinlay, to the *Belleisle*; Thomas D. Gimlette,  
 to the *Hector*.

PRESENTATION. — On the occasion of the transfer of  
 Dr. Vans Christian Clark, R.N., from the medical officership  
 of Millbank Prison to H.M. Prison for Female Convicts at  
 Woking, an illuminated address was presented to him  
 by the governor of the former establishment on behalf of the  
 officials, who desired thereby to testify their sense of the  
 value of the Doctor's services.

"Audi alteram partem."

### "THE SCOTCH UNIVERSITIES AND MEDICAL LEGISLATION."

To the Editor of THE LANCET.

SIR,—I have no pleasure in controversy with such  
 medical teachers as Professor Struthers and Professor  
 Gairdner. I shall therefore not prolong it. I will leave  
 it to you and your readers, and all seriously interested  
 in placing our medical licensing system on a better and  
 permanent basis, to judge whether my essential state-  
 ment to the Lord President does not remain entirely un-  
 shaken—that the Royal Commissioners have safeguarded  
 the just interests of the Scottish universities by adopting  
 the proposal of Professor Turner before the select com-  
 mittee, which was repeated by Professor Struthers, to  
 exempt all university students from all but the final exa-  
 mination of the conjoint boards to be established, and this,  
 Professor Struthers suggests, not to cost more than five  
 pounds.

I have never denied that Professor Struthers, Professor  
 Gairdner, and Professor Turner, prefer to be entirely left  
 alone, and to have the degree of universities recognised as  
 above the sphere of public criticism, and as, *per se*, full  
 qualifications, and entitling their holders to registration. I  
 believe that it would be safe at present so to regard uni-  
 versity degrees; but there have been times within easy  
 memory when it would not have been safe, and there might  
 easily be such times again. Universities, like corporations,  
 are only made up of men, and, like them, again, have  
 interests, sometimes of a pecuniary order, which are not  
 always the interests either of the profession or of the State.  
 It is easy to see that if some precautions are not taken in  
 the contemplated legislation, the Scottish universities, being  
 poorer than the English, would be under strong temptation  
 to enter into competition with the conjoint boards, and  
 we should have a continuance of what Sir Dominic Cor-  
 rigan called a "battle of the shops," only in a more dis-  
 creditable form than at present.

I am, Sir, your obedient servant,  
 Highbury, Dec. 18th, 1882. JAMES GREY GLOVER.

To the Editor of THE LANCET.

SIR,—In your leader of the 9th inst., speaking of the  
 Scottish universities as opposed to the Conjoint Boards, you  
 use the following words:—"They educate probably as many  
 students as all the London schools put together, and their  
 degrees, though only qualifications in medicine, entitle the  
 holders to registration. A graduate is seldom content with  
 his mere degree; he wishes to have a diploma besides, and  
 generally takes it from a College of Surgeons. Under the  
 proposals of the Commissioners he will, after passing his  
 university examinations and the clinical examination of the  
 Conjoint Board, be completely qualified, and have a honour-  
 able degree for a much less sum than he now most generally  
 pays for similar advantages and multiplied examinations."  
 The italicising is mine.

These statements are likely to convey to the minds of  
 those unacquainted with the Scottish universities the  
 erroneous impression that Scottish graduates are only half-  
 qualified. I therefore beg permission to point out that all  
 the Scottish universities themselves either teach very  
 fully both medicine and surgery or require that candidates  
 for their degrees shall have been equally well taught else-  
 where. The degrees conferred are the Bachelorship of  
 Medicine (M.B.), the Master-ship in Surgery (C.M.), and the  
 Doctorate of Medicine (M.D.); and no man has been per-  
 mitted to graduate even as M.B. alone unless he had passed  
 the full examination for both M.B. and C.M. It is usual  
 for candidates to take the two degrees. It is only a very  
 exceptional few who, being already in possession of a  
 diploma from some surgical corporation, take the M.B.  
 degree alone; and candidates for this single degree are not  
 exempted from passing any part of the full examination in

both medicine and surgery. The great body of graduates, therefore, are "doubly qualified," and do not, as you would seem to suppose, seek surgical qualification elsewhere. Now I believe it is imperative on all candidates to take both degrees. It is somewhat beside the point, but I believe I could, also, demonstrate that where the M.D. degree alone has been conferred under the regulations existing prior to 1861, it is a "double qualification"—i.e., in medicine and surgery. I am, Sir, yours faithfully,

R. M. MOFFAT, M.D., C.M. St. And.

Manchester, 18th Dec., 1882.

\* \* It is quite true, as our correspondent points out, that the Scotch universities confer the title of Master in Surgery on such graduates in medicine as wish for it. When they do so they charge an additional fee for the diploma. His view of the double virtue of the degree of M.D. under the old regulations has never been acted on by graduates or by the university. On the contrary, regarding it as only a qualification in medicine, the university devised the new title of Master in Surgery, which it confers, we believe, without any additional examination. The ingenious way in which the universities have contrived to give the virtue of a double qualification to their degrees shows how hollow and artificial the system of half qualifications is.—ED. L.

#### DR. HENEAGE GIBBES' "NEW METHOD FOR THE DETECTION OF THE TUBERCLE BACILLUS."

To the Editor of THE LANCET.

SIR,—At a meeting of the Medical Society of London last night, Dr. Heneage Gibbs exhibited some specimens of various forms of bacteria. Amongst them were several examples of the bacillus of tubercle stained in a way which Dr. Gibbs has described as "new." In the course of some remarks which I made during the meeting, I expressed my inability to perceive anything new in the method of staining the bacillus of tubercle used by Dr. Gibbs. I also said, in effect, that in the specimens of the bacillus of tubercle then before the Society I could not see evidence of any advantage in the results obtained by Dr. Gibbs' plan of mixing the ingredients of the colouring solutions in certain definite proportions. In describing what he claims as his method, Dr. Gibbs says: "It is necessary to make two staining fluids—one, magenta, which stains the bacillus; the other, chrysoidin, which stains the surrounding substance, but not the bacillus."<sup>1</sup> Now, on reading this, it certainly appears as though in using magenta Dr. Gibbs has introduced a new dye for the purpose of staining the bacillus. As is well known to those who are familiar with the subject, Dr. Ehrlich uses fuchsin for that purpose. I had always been under the impression that fuchsin and magenta were different names for the same substance. When Dr. Gibbs described his "new" method and spoke about magenta, I thought that I must have been in error, and that fuchsin and magenta were names for two different substances. On looking up the literature of the subject, however, I found that these two names are given to one and the same substance. In order to put the point beyond dispute, as regards the use of the dye in the staining of this particular bacillus, I called upon Mr. Beck, the manager of the Badesche Anilin Fabrik, 22, Bush-lane, Cannon-street, E.C. I called upon him because Dr. Gibbs says that the aniline colours are made by that company. Mr. Beck, in answer to my questions, told me that fuchsin and magenta are names given to one substance. He said that if he received an order for magenta he would supply the same substance which he would supply were an order given for fuchsin. Fuchsin, he said, is the name used on the Continent; magenta is the name in use in England. I was also told that the substance supplied by Mr. Beck to Dr. Gibbs was known in the trade by the two names, fuchsin and magenta. Mr. Beck said that Drs. Koch and Ehrlich used this same dye in their experiments. In April last Dr. Ehrlich used fuchsin to stain the bacillus of tubercle, and

my friend Dr. Koch, to me in a letter last fuchsin in this connexion for the bacillus in

It is not necessary for Gibbs' use of chrysoidin he himself informed that up the use of that substance sputum, although, he most useful when the the bacillus. In saying but that was the sense Dr. Gibbs upon this

Having given up the staining "the surrounding" Dr. Gibbs has substituted in his specimens last night of Oct. 21st last, on page Remarks on Staining writes: "I have made view of finding a good which would not at tissues too deeply. I purpose." Now, at August last (and Dr. G Ehrlich used methylene stained bacilli.<sup>2</sup> The men who were then were mentioned to me by Dr

Where, then, is the method? I suppose it which he makes on page of Oct. 21st, where he about this method which first place, the magenta compound having a diphenolrosanilin result portion of pure aniline is commonly called, a definite compound is a colour from the bacilli stable compound is used plasma alone is stained, like bodies only are seen the whole organism is stained rod-shaped bacillus colonies (?spores)." I rosanilin results; but let rest of this statement, in cess, I can only say that own experience. I have produced by that process of head-like bodies only vast majority of the organs

Dr. Gibbs asserts that colour does not fade from does fade where Ehrlich that when men first with bacilli did, now and the early experience that he different now. Ehrlich's quite as good results as an illustration I may mention specimens which June last for exhibition College of Physicians. aniline colours will, but distinct. As M. Vignat upon this subject, "When colour fades with equal tion be adopted or not."

Dr. Gibbs also claims use the bacillus can be with an ordinary quarter According to him, when bacillus is so faintly stained illumination is required in factory manner." This is surprising statements. showed the bacillus, previously last at the Royal Medical quarter-inch object glass.

<sup>1</sup> British Medical Journal, Oct. 14th, 1882, p. 736.

<sup>2</sup> British Medical Journal

bacillus under an ordinary quarter-inch object glass, and a very ordinary London daylight as my only illuminator. It is not very surprising to find that Dr. Gibbs has so poor opinion of Ehrlich's process when one reads his description on page 736 of the *British Medical Journal* for 14th. It runs thus: "In Ehrlich's process the stain the bacillus is too faint, and the vesuvium used to stain the substance too opaque; consequently the bacillus has a faint pink colour on a dense yellowish-brown ground, and is not easily made out without high power or artificial illumination." If with Dr. Ehrlich's process the staining of the bacillus is found to be too faint, the fault lies with the experimenter and not with the process. August last Dr. Gibbs evidently did not know what was meant by Ehrlich's process, else he would surely never have said that at that time, or for months before that time, Ehrlich used vesuvium to give a "dense yellowish-brown ground," to a bacillus of a "faint pink colour." Since April Dr. Ehrlich has used methylene blue as a contrast colour for red stained bacilli.—I am, Sir, yours faithfully,  
G. A. HERON.  
London, Dec. 5th, 1882.

### "PICRIC ACID AND SUGAR TESTING."

To the Editor of THE LANCET.

SIR,—In reply to Dr. Pavy's imputation on my memory I beg to allow me to say that I have neither denied nor admitted the existence of unoxidised sulphur compounds in normal urine, but in answer to his statement that the presence of such compounds "means, in other words, the incapacity for producing a sulphide on boiling with potash," I ask him for some proof of this other than a reference to unknown text-books. He may, perhaps, consider that in describing the reaction which occurs on boiling normal urine with liquor potassæ mixed with lead, he has given sufficient proof; but Dr. Pavy will doubtless admit that practically there is a very wide difference between the blackening of albuminous urine when boiled with lead-contaminated potash, and the slight and even doubtful colouration which results from treating normal urine in the same way. And I ask him to give careful consideration to my son's error in your last number, where he has shown that prolonged boiling of normal urine with caustic potash, while it destroys the sugar, does not form an alkaline sulphide. I request his particular attention to the facts and arguments contained in this week's letter from my son. He demonstrates and explains the fact that while a lead sulphide is formed by boiling albuminous urine with liquor potassæ mixed with lead, no alkaline sulphide is formed in the same urine is boiled with pure liquor potassæ. This observation explains the fact mentioned in my last letter to you, that albuminous urine containing the normal proportion of sugar—i.e., about 5 of a grain per ounce, gives exactly the same depth of colour when tested with picric acid and potash as the same specimen after the removal of the albumen by coagulation and filtration. I beg now to thank Dr. Pavy for his friendly criticism, the result of which has been to elicit a more speedy and complete demonstration than without it would probably have been given—that there is no substance, either in normal or in albuminous urine, to interfere with, or to render in any way fallacious, the picrate test for sugar. I hope in the course of a few days to send you a detailed description of a method of quantitative analysis of saccharine by which I obtain results practically identical with those arrived at by my son, who analyses the same specimens by means of Dr. Pavy's ammonio-cupric method. The advantage which I claim for my method is that it requires only a very simple and inexpensive apparatus, that it is easily learnt and practised, and that by its means an exact analysis of a sugar solution may be made in about five minutes.—I am, Sir, yours faithfully,  
GAVILLE-ROW, Dec. 18th, 1882.

GEORGE JOHNSON.

To the Editor of THE LANCET.

SIR,—The argument employed by Dr. Pavy in his communication to you of the 12th instant is that, as an alkaline sulphide is produced by boiling albumen with caustic alkali solution, so an alkaline sulphide will likewise be formed by the action of boiling potash upon those unoxidised sulphur compounds which have been proved to exist in healthy urine,

and which are presumably nearly allied to albumen in their chemical properties and constitution.

Now it is stated and accepted as a fact in the chemical text-books, and is to be found in so many words in "Watts' Dictionary," that albumen gives rise to an alkaline sulphide when boiled with solution of caustic alkali. It was, therefore, very surprising to me to find that dried ovalbumen, a specimen of which happened to be handy, produced no trace of sulphide even after boiling for half an hour with a strong solution of potash; the solution thus obtained gave no dark colour or precipitate with a solution of acetate of lead, and no reaction with nitro-prusside of sodium, even after diluting the liquid till the excess of caustic alkali was no longer sufficient to interfere with the production of the characteristic colour on the addition of a single drop of H<sub>2</sub>S water.

At first I was inclined to doubt whether the specimen of albumen employed had not been subjected to some process which had deprived it of its sulphur, but this idea was at once negatived by the fact that if the lead solution was added to the albumen and potash before boiling, and heat afterwards applied, an abundance of lead sulphide was produced. And here is the clue to the mystery. The text-books direct to add the lead before boiling the albumen with potash. The fact is that a sulphide can be produced only by boiling an alkaline solution of albumen (made in the cold) with a metallic solution, such as one of lead or copper. Clearly the sulphur of the albumen is converted into some sulphur salt of potash (not sulphide) by boiling with caustic potash, for the solution thus obtained gives no sulphur reaction with the picrate test, lead test, or nitro-prusside test.

Taking into consideration the importance of this observation, and especially the fact that it contradicts accepted statements concerning the action of alkalis upon albumen, it was thought necessary to establish the fact by yet further, and if possible, more convincing evidence. With this end in view I performed the following experiment:—Some of the alkaline albumen solution, obtained by prolonged ebullition of white of egg with caustic potash, was placed in a two-necked Woulfe's bottle and a stream of pure carbolic anhydride gas passed through it till all air was expelled. This having been accomplished, the liquid was rapidly acidulated with pure acetic acid, and the issuing gas caused to bubble through a slightly acidulated solution of lead acetate. Not the faintest turbidity was observed after prolonged passage of the gas through the lead solution, and no darkening of colour, though the issuing gas possessed a peculiar fetid odour. This test is, of course, one of extreme delicacy, the CO<sub>2</sub> gas tending to carry on with it any gas that might be in solution in the acid liquid, and at the same time preventing the possibility of any H<sub>2</sub>S being oxidised by the air. Anyone may convince himself that these observations upon the albumen of the egg apply equally to the serum albumen found in albuminous urine. Place some albuminous urine in two test-tubes, add to one test-tube some caustic potash and a few drops of acetate of lead solution, whilst to the other an equal portion of caustic potash is added, but no lead. Then boil the contents of both tubes for three or four minutes, and add to the liquid containing potash and urine only, a quantity of lead equal to that added to the other tube. It will be found that the liquid to which the lead was added after boiling remains clear (the colouring matter is somewhat reddened, but no sulphide of lead is formed), whilst the other solution will be blackened by lead sulphide in proportion to the quantity of albumen in the specimen under examination.

It seems, then, that no sulphide is produced by boiling even albumen with caustic alkali, unless a metallic solution be added previously to boiling, and as no metallic solution except the potash is employed in the picrate test, it follows that the presence of albumen in urine can in no way interfere with the application of this test to the detection or quantitative estimation of grape sugar therein. And in this respect the picrate test possesses a manifest superiority over that of Fehling.

I am, Sir, yours truly,

G. STILLINGFLEET JOHNSON.

King's College, Dec. 18th, 1882.

### "DEATHS AFTER ABDOMINAL OPERATIONS FROM HEART-CLOT."

To the Editor of THE LANCET.

SIR,—Mr. Lawson Tait declines to enter into the question raised by my reading of his cases of death from heart-clot, and shelters himself behind the easy device of the denial of

the septic condition. His previous description of the cases will go farther with most people in deciding what was the cause of death than his present mere denial of septicity. Mr. Tait claims that his recently published statistics show that abdominal operations do far better without Listerism than with it. I dispute this statement entirely; and in proof of my right to do so I give the following ovariectomy statistics. I only myself became aware of the actual state of the case on collecting these statistics recently at the request of a distinguished American surgeon.

*Ovariectomy Statistics.*

		Recoveries.	Deaths.	Mortality per cent.
Keith's cases,	381	340	41	10.76
Thornton's „	328	293	35	10.67
Tait's „	226	199	27	11.94

I take Dr. Keith's figures from his letter to Mr. Spencer Wells (Oct. 1881, "Ovarian and Uterine Tumours," p. 224). My own statistics are down to date. Mr. Tait's are taken from his successive published tables, and end with a case operated on on August 5th, 1882. If the fact of my giving my own to date improves my relative position, it only proves that recent Listerism in my practice has done more for me than the discarding it has done for Keith and Tait. I have asked the former for his later statistics, and have received no reply; so that if including them would have improved his percentage, the fault does not rest with me. The results are curiously close; but the fact remains that my practice of consistent Listerism gives me a slight advantage in percentage mortality over Dr. Keith, and a more marked one over Mr. Tait. If the antiseptic and non-antiseptic cases of each operation are separated into two classes, the value of Listerism becomes still more evident, but to do this fully would take up too much space in a letter. I believe that if Dr. Keith had stuck to pure Listerism, he would have reversed our respective positions. From Mr. Tait's own statements to me about his wounds, when he was supposed to be practising Listerism, and from his many public utterances on the subject, I do not believe that he has ever been able to grasp the true meaning of Listerism, or ever really to practise it.

If we turn now from ovariectomy statistics to those of oöphorectomy, Mr. Tait's special operation, and one in which he has had a larger experience by far than I have (and Mr. Tait has always had the greatest faith in the effect of experience on success), we find that in his first seventy cases Mr. Tait had six deaths, or a mortality of 9.57 per cent. And one of the deaths which started this correspondence also results from oöphorectomy. I, on the other hand, with a much smaller experience of fourteen oöphorectomies, with careful Listerism have not had a single death. Mr. Tait's mortality, then, is nearly 2 per cent. higher than mine in ovariectomy, and 9½ per cent. higher in his special operation of removal of the uterine appendages. With regard to the action of carbolic acid on feeble kidneys, I can only say that I have not met with the dangerous results which have befallen Dr. Keith, Mr. Tait, and Dr. Bantock. And I can tell Mr. Tait that the informant, whoever he may be, who caused him to write as follows, "I have heard that Mr. Thornton's own experience has been unfortunate in this direction," has led him into a statement which has no foundation in fact. I have not had reason to believe that any of my cases have seriously suffered from the use of carbolic acid, though I have performed nearly two hundred Listerian abdominal sections since I last published my results. There is also, I am glad to say, a marked falling off in septicaemia as compared with my last published one hundred and seventy-two antiseptic abdominal sections.<sup>1</sup> With regard to the quotation which Mr. Tait makes from Mr. Wells's book, anyone who reads the whole paragraph will see that its sense is very different from the portion of it which Mr. Tait has separated from the context, and the fact remains that Mr. Wells continues to use full Listerian details, including the spray, and is, as I know from a recent conversation with him, well satisfied with the results he obtains, and he, like myself, has not met with any of those remarkable deaths from diseased kidneys which tell so seriously upon the statistics of Dr. Keith, Mr. Tait, and Dr. Bantock.

I will tell Mr. Tait why operations such as the one of the

<sup>1</sup> Medico-Chirurgical Society's Transactions, vol. lxiv.

success of which he boasts because we consider him endangered; and our fibroid are only just endangered by the disease was under my care in the She was then forty-three ment of the uterus, with symptoms of any kind. from Oct. 1st to Oct. 1st her against operation, died in placing her life much worse, and that cure at the menopause years which have elapsed become very much worse, quoting the case as having to operate. Perhaps "huge and rapidly growing and the other urgent symptoms. I have just advised two uterine fibroids, both from England, and both sent. They were healthy women operation by recovery, I putting them to the same a brief note of these two. clusion, I have to thank afforded me of demonstration by Listerism in ovariectomy.

The annual meeting of Royal Infirmary was held favourable financial statistics patients treated as 1693. now in course of completion is already almost in hand expenditure will provide tional beds. The report reference to Drs. Johnston

Since the establishment at Aberdeen, five years rapidly to grow. Comm are now thirty, and there that there is seldom an e for further accommodation

, as well as to carry out the wishes of a handsome contributor to the funds, the directors have determined upon extensive additions to the building. At present no provision is made for the isolation of cases of infectious disease which may occur, and for this purpose a separate building is proposed. Anyone visiting the tidy and cheerful wards will see at a glance how zealous and enthusiastic is the management. Drs. Stephenson, Garden, and Macgregor on the staff; but no one will more readily than these gentlemen admit the large share of the hospital success which is due to the kind care of Miss Lumsden, the matron.

The pathology question was again before the managers of the Aberdeen Infirmary on the 11th inst. It will be remembered that the new professor of pathology requested access to the material for instruction afforded by the infirmary, but the considerable difficulty in the way was that the institution was already served by a pathologist who has done the work most acceptably for some twelve years—there was, in fact, no vacancy in the office of pathologist. In May last the whole subject was remitted to a committee to report, and they ascertained that Dr. Deger was willing to offer every facility to the professor in the use of material from the dead-house and the museum. The committee, by a majority, reported in favour of Dr. Deger retaining his present position, but that Professor Milne should make half the post-mortem examinations. This compromise is so evidently unsatisfactory that the managers willingly agreed to the motion of Dr. Struthers, that the whole subject should lie over for three months, in the hope of a private settlement. Everyone will feel relieved should the matter be thus amicably arranged; but it is highly important that able and active officers should have a feeling of insecurity in their position; and certainly a precedent would be established were Dr. Rodger suddenly removed from office, or felt himself called upon to resign in consequence of undue pressure. The question of the appointment of an assistant-physician has been postponed.

As the new material celluloid is coming into use in the manufacture of catheters, tracheotomy tubes, &c., it may not amiss to mention the narrow escape from a disagreeable accident which a patient of mine had a few days ago. The catheter seemed so suitable for use by my patient himself, that I placed it in his hands, and in this way it had been passed a very few times. As it was the first of this kind which I had used I was curious to know my friend's experience, and on examining the instrument before use quickly detected a crack, which went almost completely round the tube. A few inches of a broken catheter in an unexamined bladder would have been exciting enough, and the notion of my escape may place others on their guard.

## IRELAND.

(From our own Correspondent.)

THE following "resolution" of the Council of the Royal College of Surgeons was adopted on the 7th inst.:—"That the Inspection Committee be instructed not to receive certificates from any school in which evening lectures are delivered." This resolution naturally created great dissatisfaction among a numerous class of students, those attending evening lectures on account of being engaged in business during the day. That no notice had been given by the College until after November 25th, the last day for registering students, was looked on as an additional hardship, as there was no time to enter at any other recognised school of medicine. A meeting of those interested was held, and a memorial prepared for presentation to the Council. Accordingly, a deputation of night-students had an interview with the Council of the College on the 14th inst., and stated their views through the spokesman, Mr. Carroll, who pointed out the hardship which must necessarily ensue should the Council refuse to modify their resolution. A division of the Council afterwards took place, when only two members voted for excluding night-students altogether, while the remaining members voted for their recognition during the present term. The following resolution was then adopted:—"That the resolution of December 7th in reference to night lectures shall take effect from April 1st, 1883, after which it

shall be strictly enforced." It is believed that if the deputation had asked for better terms they would have obtained them; and there are some, and not a small number either, who are of opinion that any resolution of the College refusing to receive certificates of night lectures is altogether illegal, and could not be upheld if properly opposed.

The returns for the five medical schools in Dublin show that the Ledwich still holds the highest place as regards the number of students receiving instruction within its walls. The following are the numbers for the present session: Ledwich, 230, or 9 increase; Trinity College, 225, or 9 increase; Carmichael, 134, or 25 decrease; College of Surgeons, 132, or 8 decrease; Catholic University, 116, or 16 increase. These make a total of 837, or exactly one more than those registered in the session of 1881-2.

The Medical Section of the Academy of Medicine held its first meeting at the College of Physicians on the 15th inst., when the President of the Section, Dr. William Moore, President of the College, delivered the inaugural address. Dr. Moore spoke of the improvements in the diagnosis of disease which had taken place during the past twenty-five years. He referred to the thermometer, which was often of service in difficult cases, and alluded to the advances made in the diagnosis of cardiac disease. He believed that the prognosis depended less upon the various murmurs heard than on the vital condition of the organ itself, the prognosis being more important than the diagnosis. He next referred to Claude Bernard's experiments, which had thrown light on various affections, and spoke of abdominal aneurism, the specific nature of fevers, bacilli, and of cerebral and spinal diseases. It was sometimes very puzzling to diagnose between organic and functional diseases; and he detailed various cases which occurred in his practice as examples of the difficulties occasionally met with.

Last week, Mr. Harrington, master of the Carrick-on-Shannon Workhouse, and his wife were found dead in their bed. A fire had been lighted in their bedroom the previous evening, and the fatal result was attributed to the imperfect ventilation of the apartment, and the large amount of deleterious gases given off from the coal, which was of a very inferior kind.

During the September quarter the returns of pauperism in Ireland show a decrease of 1174 in the number of workhouse inmates, and an increase of 810 in the number of persons on out-door relief as compared with the previous quarter. The prevalence of the following zymotic diseases was reported by the various registrars:—Measles in 56 districts, scarlatina in 40, diphtheria in 4, and fever in 53. Three deaths from hydrophobia were recorded during the quarter.

The late Dr. Handzel Griffiths, who was Assistant-Librarian to the Royal College of Surgeons, died from typhoid fever in 1877, and since then his wife has also died, leaving three orphan children behind her with but scanty means of support. A committee has been formed to collect funds for supporting and educating the three boys, and as the case is a deserving one, it is to be hoped that the amount required will be obtained.

The death is reported of Dr. John Burgess Allen, of Gorey, a well-known practitioner in that place. Deceased, who was in his fifty-third year, succumbed from congestion of the lungs.

## PARIS.

(From our Paris Correspondent.)

THE discussion on typhoid fever which has been carried on at the Academy of Medicine for the last two months is, like the prevailing epidemic, on the wane. I shall endeavour to summarise it as briefly as possible in this letter. The first part of the discussion was taken up with the etiology of the disease, most of the orators being evidently converted to the faecal, or what the French authors are pleased to term the English, theory of its origin. Dr. Noël Guéneau de Mussy is the principal representative of the English theory, and he endeavoured to prove that typhoid fever in general, and the present epidemic in particular, may be clearly traced to the contamination of drinking water and alimentary substances by dejections of patients suffering from the disease. This theory Dr. Guéneau de Mussy has sustained for several years, and in 1877 he made a com-

munication to the Academy of Medicine in support of it. He believes more than ever in the English theory; but he thinks, also, that the germ of typhoid fever may have another habitat or another medium for its culture. Founding his arguments on this view, he insisted on a more scrupulous attention to sanitary measures, both public and private, particularly to the privies and cesspools. The latter he totally condemns, as, also, the practice, introduced into this city about twenty years ago, of emptying their contents into the sewers, which, in their turn, are emptied into the Seine. Dr. Rochard, an old academician, endeavoured to show, in the most eloquent terms, that while he conceded the probable correctness of the theory of the faecal origin of typhoid fever, there are other elements to be taken into consideration which, no doubt, play a great part in the development of the disease, such as cosmic influences, overcrowding, and want of cleanliness; but he does not wish it to be inferred from this that he believed in the spontaneity or the production of the disease *de novo*, adding that the microbe of typhoid fever exists in the air and develops itself as soon as it can find a favourable soil. Other speakers followed, all sustaining, in more or less definite terms, the theories above enunciated. M. Jules Guérin then came forward, and suggested that, in the present state of our knowledge of the etiology of typhoid fever, it would be of more practical interest and utility to discuss the means, on clinical grounds, by which the disease may be successfully combated, instead of wasting time in going over the already frequently trodden ground.

As to the therapeutics of typhoid fever, Professor Hardy stated his preference for the old classical treatment, which consists of the administration of purgatives during the first ten days; the application of dry cupping to the chest; draughts composed of extract of cinchona and alcohol; and of acidulated drinks during the second and third weeks. He sometimes prescribes the sulphate of quinine, but never exceeds 75 centigrammes, or about eleven grains daily. Dr. Hérard had always obtained good results from the administration of quinine, but in larger quantity than that employed by Prof. Hardy—as much as three or four grammes, or about one drachm daily. He also prescribed salicylic and carbolic acids in minute doses, which he considers powerful antiseptics and antipyretics. Dr. Legouest believed that the proper quantity of quinine in these cases would be two grammes (thirty-one grains) daily, which he learned from long experience in the military hospitals; and is inclined to think that when sudden death occurs in typhoid fever, it is attributable to the malignancy of the disease itself. Most of the speakers seemed to lay great stress on the necessity for reducing by every possible means the excessively high temperature that exists in this fever, by the employment of salicylic and carbolic acids, and the use of cold baths; but, according to Dr. Dujardin-Beaumetz, hyperpyrexia is certainly a manifestation of the gravity of the disease, and to treat this manifestation only would not constitute the proper treatment, as the temperature would be simply kept in abeyance by the remedies employed, but the disease would continue its course all the same. Moreover, he asserted that it was impossible to lay down any definite rules for the treatment of this terrible affection, but patients must be treated according to existing indications, as in all epidemics there is a certain morbid agent, something unknown, which renders them so different from one another. That which distinguishes the present epidemic of typhoid fever in Paris, is the frequency of bedsores over the sacrum, which reminded one of the description given by Trousseau, and also the frequency of diphtheritic symptoms. Under these circumstances the statistics of the treatment employed would be of little or no value. Dr. Dujardin-Beaumetz was of opinion that in these cases simple "expectation" would be far preferable to the use of powerful remedies which may be more harmful than otherwise. Professor Vulpian, after having given a fair trial to some of the drugs reputed to possess antiseptic properties—iodoform, boracic acid, salicylate of bismuth, the carbolate of soda and salicylic acid—has given the preference to the latter, and administers it in doses of five or six grains every two hours, or six or seven grammes in the twenty-four hours. He has employed it on account of its known property of lowering the temperature, which it does in a more persistent manner than carbolic acid or any of the other substances named. The general state of the patient is favourably modified, but the duration of the malady does not appear to be sensibly influenced by the treatment. M. Vulpian, how-

ever, concludes that, considered as a curative agent sufficiently modifying to a place among the treatment of this such that he would, during epidemics of typhoid fever, administer it even to daily. Professor Germain, acid internally, not other form of disease of the vital forces, producing toxic effect the heart which it de considers salicylic acid fever, whether as at these indications he of quinine, which he daily; a larger quantity smaller would be use the following as a t adopts what he term baths, administering and in case of excited tincture of opium in and a half, which he of the disease in patients in individuals worn combats tympanites water; complications and ipecacuanha. Actions he employs even time aids in lowering carbolic dressings in the disease. Of fifty Dr. Lancereaux from of November only five Paris, Dec. 19th, 1882.

## TENEMENT

(From a  
(Co

AT Boston, Mass., been done to secure the be regretted, however Health Commissioners arrangements and con that city. In consequence established a separate are referred, the sanitary houses leave much to be of the townspeople. In responsibility, and in concerned to separate sanitary condition of Department, is almost, to separate the dieting physician who has charge from which he is suffering administrative mistake certainly entitled to raise its culture and sound only to be called to rectification. Nothing best interests of the city and the sooner it is the health of the city. Health for the good during the past ten years quarantine arrangement a genuine enthusiasm for to ensure the health keeps its streets and the Still, when all this is and it is not a little remarkable for the construction in Boston is much behind

for an concerned.

In New York, up to the year 1878, the tenement house was not only a scandal but a danger to the public health. Even to-day the condition of affairs is not satisfactory, and in spite of the energetic action of one of the most capable of Boards of Health to be found in the United States, much remains to be done. Here, as in Liverpool, the difficulty is to provide suitable accommodation for and to restrain the large floating population which constitute the dregs of the emigrant class. In a tenement house in Mott-street situated almost exactly opposite the offices of the Board of Health, and plainly visible therefrom, is situated a tenement house, or rather houses, which are as bad as anything to be seen anywhere to-day. They are occupied by Italians, but though poor the people themselves are fairly cleanly, and their rooms are at times, considering their surroundings, wonderfully clean. The closets, however, are in a disgraceful condition, and present a spectacle as filthy as the slough of despond itself. This state of affairs could be remedied; it has been vastly improved at Boston, and it is not credible that New York should long lag behind. Unfortunately there are many of these tenement houses in New York, and little hope is held out of their extinction or removal. Much good has, however, been done since 1878 when the *Sanitary Engineer* drew public attention to the condition of the New York tenement houses, and offered a prize of \$500 for the best design for such a building. This competition excited keen interest, and resulted in much improvement. Public attention was aroused, clergy and laity combined to urge reform. A joint committee, consisting of the judges and a committee of the State Charities' Aid Association, was formed, and in the result an amendment to the Tenement House Act was passed by the State Legislature in May, 1879. This Act limited the space to be occupied by any tenement house to sixty-five per cent. of the lot it occupies, required all bedrooms to have windows, with direct light and air, and greatly increased the powers of the Board of Health to remedy the abuses in such buildings. Two associations were formed to erect model dwellings for working men, and several improved tenement houses have been and are being erected by private individuals. No plan can be settled now without the approval of the Health Department, and all plans which fail to meet the requirements of the law are invariably rejected. All this is most satisfactory; and it would be unjust to omit to mention the fact that these results are largely due to the liberality, earnestness, and zealous labour of Mr. H. C. Meyer, whose whole-hearted and disinterested exertions

should not pass without public recognition. A visit paid to one of the blocks recently erected by the Improved Dwellings' Association afforded many satisfactory proofs of the way in which these buildings are appreciated by the class for whom they have been erected. The dwellings of this company are situated on First Avenue, and consist of thirteen houses of six storeys each, with basements used as cellars and laundry. There is here accommodation for 218 families in suites of two, three, and four rooms, which are rented at from 8s. to 16s. per week. There are a laundry, reading-room, and bath-house connected with these buildings, and there is ample playground for the children. Care has been to make the sanitary arrangements perfect; but a casual visit leads to the conclusion that at present the soil-pipes have to be better ventilated and the drains to be properly disconnected from the main sewer before the health of the inmates is likely to continue good. These buildings were opened in May, 1882, so the managers have had but a short experience of the working. The mortality amongst the children, of whom 400 have been residents, has been a total of three deaths, and out of 218 sections no less than 157 have been occupied. There is a slight discipline enforced. Irish people, who are unable to give a clean bill of health as to drink, all scolds, and mothers who cannot control their children, are not admitted. The refusals are in practice very few, the night janitor reports all cases of drunkenness, and after two cautions a third offence is visited by a notice to quit. Credit is not given except in case of death or sickness. There are resident at the present time within the buildings twenty-one French Canadian families, who are reported to make excellent tenants and to be very respectable. I wish the project every success, and judging from what I saw this association deserves and will obtain it. The great difficulty in New York is the expense of sites, land being so valuable, and this circumstance is likely to delay the erection of an ample quantity of suitable tenement houses.

In Philadelphia there are practically no tenement houses, as here land is plentiful, and it is the fashion for every man to own the house in which he lives. Hence, poverty is rare, thrift is everywhere apparent, and the large number of small houses or pretty cottages fills the visitor with astonishment. It would be a grand thing if every father of a family could own his own house as he does in Philadelphia. This is something for us to aim at accomplishing where possible, and its general adoption would be indeed an approach to the millennium. It is not possible to obtain this in England, but in Ireland and America the general adoption of this Philadelphia system is greatly to be desired.

## Medical News.

**ROYAL COLLEGE OF SURGEONS OF ENGLAND.** — At the last meeting of the Council, the following gentleman, who passed his examination for the Fellowship in May last, having attained the legal age of twenty-five years, was granted his diploma of Fellow of the College:—

Firth, Robert Hammill, L.R.C.P. Edin., Ware.

[The letters following the name of Arthur Bancks Prowse, in the list published last week, should have been "M.D.," not "M.B."]

**UNIVERSITY OF LONDON.** — The following candidates have passed the recent M.D. Examination:—

\*Buckell, Arthur Edward, University College.  
Collins, Wm. Job, B.S., B.Sc., St. Bartholomew's Hospital.  
Dalton, Norman, King's College.  
Davy, Henry, Guy's Hospital.  
Dickinson, Thomas Vincent, St. George's Hospital.  
Edwardes, Edward Joshua, St. Mary's Hospital.  
Firth, Charles, St. Bartholomew's Hospital.  
Gabb, James Percy Alwyne, University College.  
Hobson, Lewis John, B.S., University College.  
MacDonald, Greville Matheson, King's College.  
Maguire, Robert (Gold Medal), Owens College and Manchester Royal Infirmary.  
Notley, William John, B.A., Edinburgh Royal Infirmary.  
Paddison, Edmund Howard, Guy's Hospital.  
Parkes, Louis Coltman, University College.  
Penny, Edward, Guy's Hospital.  
Petch, Richard, King's College.  
Plumbe, Samuel Thomson, St. Bartholomew's Hospital.

Railton, Thomas  
Owens College

undermentioned Licentiates were admitted to the membership of the College:—

Edw. Geoghegan, R.N.	John Byrne Power.
John Joseph Mullen.	William Tobin.

George St. George Tyner.

**POTHECARIES' HALL.**—The following gentlemen passed the examination in the Science and Practice of Medicine, and received certificates to practise, on Dec. 14th:—

Buckley, Thomas William, Betley, near Crewe.  
Canton, Herbert, Camden-road.  
Dodd, Henry W., Hildrop-crescent, Camden-road.  
Ledlie, Andrew, Belfast.  
O'Kane, Michael, Gaulock-road, Camberwell.  
Perry, Allan, Poplar Hospital.

The following gentleman also on the same day passed the Medical Professional Examination:—

Crisp, James Ellis, London Hospital.

**ANOTHER CENTENARIAN.**—A woman in Kendal, named Sarah Birkett, has just died at the reputed age of 100 years.

**VACCINATION GRANT.**—The following gentleman received the Government grant for efficient vaccination: Dr. G. R. Barnes Ewell, Surrey (fifth time).

**CHARLETON FEVER** is very prevalent at Tebay in Lancashire. The authorities seem to be awake to the necessity of strenuous efforts to cope with the disease.

**HOSPITAL SUNDAY** at Hull has yielded the largest collection yet taken in that town—viz., £788 14s. 9d. Last year the amount was £694 11s. 5d.

On the 15th inst. the new wing lately added to the Midland Infirmary was formally opened by the Mayor of the town. About £2000 remains to be collected to cover the cost of the improvement.

At the last meeting of the Middlesborough Town Council it was agreed, on the recommendation of the Watch Committee, to advance the salary of the Police Surgeon (Mr. M'Cuaig) from £52 to £75 per annum.

The governors and trustees of the York County Hospital have voted £300 towards improving the sanitary condition of the hospital, in accordance with the advice of the medical staff and the recommendation of Mr. Slater, sanitary engineer, of York.

**NORTH-WEST LONDON HOSPITAL.**—The following appointments have recently been made to this hospital, Kentish Town Road:—Skinners' Company, £10 10s.; Vintners' Company, £10 10s.; Haberdashers' Company, £10 10s.; Mercers' Company, £26 5s.

The governors of the Hastings, St. Leonards, and East Sussex Infirmary have decided to accept the gift of a large mansion to be converted into a convalescent home, and also to build a new infirmary on the site of the existing structure, capable of accommodating seventy-five patients.

## Medical Appointments.

Communications for this column must be sent DIRECT to the Office of THE LANCET before 9 o'clock on Thursday Morning at the latest.

**NOLD, RICHARD O.,** L.F.P.S.Glas., L.S.A.Lond., has been appointed Medical Officer for the Workhouse, Luton, Beds.

**INTERHAM, J. W.,** M.B., B.S.Lond., M.R.C.S., has been appointed House-Surgeon to the South Staffordshire and Wolverhampton General Hospital.

**ERS, JOHN W.,** M.A., M.D., M.Ch., M.R.C.S., L.M.K.Q.C.P.I., has been appointed Physician for Diseases of Women to the Royal Hospital, Belfast.

**HEY, EDWARD,** M.D., B.S., has been appointed Medical Officer of Health to the Borough of Windsor, vice S. Turrell, M.D., deceased.

**ADWICK, GEO. F.,** M.R.C.S., has been appointed House-Surgeon to the Dewsbury and District Infirmary, vice Evans, resigned.

**GRAVE, E. MACDOWEL,** M.D., L.K.Q.C.P.I., has been appointed Physician to Whitworth Hospital, Bishop's-road, Dublin.

**DAVIDSON, ALEXANDER,** L.F.P.S.Glas., has been appointed Medical Officer for the Anstey District of the Tamworth Union.

**EMMERSON, WILLIAM LINDSAY,** L.M.Dur., M.R.C.S., L.S.A.Lond., has been reappointed Public Analyst for the Borough of Stamford.

**EVANS, S. E.,** L.R.C.P.Ed., L.R.C.S.Ed., has been appointed Resident Medical Superintendent of the Bradford Fever Hospital, vice W. K. Rix, resigned.

**FENWICK, E. HURRY,** F.R.C.S., has been appointed Demonstrator of Physiology to the London Hospital Medical College.

**HALL, CHARLES B.,** M.D., has been appointed Honorary Physician to the Dewsbury and District Infirmary.

**HERON, G. A.,** M.D., M.R.C.P., has been appointed Senior Assistant-Physician to the City of London Hospital for Diseases of the Chest, vice S. West, M.D., M.R.C.P., appointed a Physician.

**HOBSON, LEWIS JOHN,** M.D.Lond., B.S., has been appointed Honorary Physician to the York County Hospital.

**HOPE, E. W.,** M.D., B.Sc.Ed., has been appointed House-Physician and Pathologist to the General Hospital, Wolverhampton.

**JORDAN, FRED. WILLIAM,** L.R.C.P.Lond., M.R.C.S., L.S.A.Lond., has been appointed Medical Officer of Health for the Heaton-Norris Urban Sanitary District, vice Bird, deceased.

**KEYWORTH, JOHN WHITE,** M.D.Lond., M.R.C.S., L.S.A.Lond., has been elected Physician to the Wellington Hospital, New Zealand, vice Dr. Collins, appointed Surgeon.

**NELSON, J. M.D.,** has been appointed Ophthalmic Surgeon to Belfast Royal Hospital.

**PELLEW, EDWARD BRAY,** L.R.C.P.Ed., M.R.C.S., has been appointed Medical Officer for the Eastern District and Workhouse of the Hailwhistle Union, vice Walker, resigned.

**RIDPATH, D.,** M.D., has been appointed Medical Officer of Health for the Rural Sanitary District of the Great Driffield Union.

**SHAW, JOHN ALEXANDER,** M.R.C.S., L.S.A.Lond., has been appointed House-Surgeon to the Victoria Hospital for Children, Chelsea, S.W.

**STEELE, R.,** L.R.C.P.Ed., M.R.C.S., has been appointed Medical Officer for the Third District of the Lutterworth Union.

**WHITE, SINCLAIR, M.D.,** M.Ch.Q.U.I., has been appointed Lecturer on Physiology in the Sheffield Medical School.

**WILLIAMS, C. J.,** M.R.C.S., has been appointed Medical Officer for the Fifth District of the Lincoln Union.

## Births, Marriages, and Deaths.

### BIRTHS.

**ANGUS.**—On the 19th inst., at North Ashfield, Newcastle-upon-Tyne, the wife of James Acworth Angus, M.R.C.S.Eng., L.S.A.Lond., of a son.

**IRONSIDE.**—On the 18th inst., at Highbury New-park, the wife of R. A. Ironside, M.B., C.M., of a daughter.

**MCINTYRE.**—On the 15th ult., at Avoca House, L. Unchlanga, Natal, S.A., the wife of John McIntyre, M.D., of a son.

**PERKINS.**—On the 5th ult., at Exmouth, Devon, the wife of George Steele Perkins, M.B., C.M.Edin., M.R.C.S., L.R.C.P.Lond., of a son.

### MARRIAGES.

**DAUNT-NICKOLL.**—On the 12th inst., at St. John's Church, Pembroke Dock, South Wales, Elliot Daunt, L.R.C.P.Lond., M.R.C.S., &c., of Pierpoint House, Lindfield, and third son of the Rev. E. S. T. Daunt, of St. Stephen's, Launceston, to Eleanor Maude Mary, only daughter of J. Nickoll, Esq., of Pembroke Dock, and granddaughter of the late Commander J. Harvey Nickoll, R.N.

**LAING-HARDING.**—On the 13th inst., at Madras, Surgeon-Major James Anderson Laing, Indian Medical Department, to Mary, third daughter of G. P. Harding, Esq., of Champs Elysées, Paris.

**POYNDR-NISBETT.**—On the 18th ult., at Landour, N. W. India, George Frederick Poynder, Surgeon, A.M.D., eldest son of the Rev. L. Poynder, retired Chaplain in India, to Mary, daughter of Major-General Nisbett, B.Sc., of Shirley, Southampton.

### DEATHS.

**FAWSETT.**—On the 18th inst., at Wisbech, Frederick Fawcett, F.R.C.S., in his 76th year.

**LAWRENCE.**—On the 30th ult., at Claverton-street, Bath, George Edgar Lawrence, M.R.C.S.E., L.R.C.P.Lond., aged 32.

**LLOYD.**—On the 11th inst., at Tyn Rhyl, Rhyl, Edward Lloyd, M.D., L.R.C.P., formerly of Castella, Glamorgan, aged 62.

**PATERSON.**—On the 9th inst., suddenly, at Bahia, Brazil, John Lijertwood Paterson, M.A., M.D., M.R.C.S.E., of Boa Vista, the Grange, Edinburgh, aged 62. Friends at home and abroad will please accept this intimation.

**SHEPHERD.**—On the 12th inst., at Beach Cottage, Teignmouth, Fleet Surgeon Charles Douglas Shephard, R.N., aged 61.

**WEST.**—On the 17th inst., at Cairo, Edward de Lancy West, M.B., C.M.Edin., the dearly-loved and only son of the Rev. Dr. West, of Epsom College, aged 26.

**N.B.**—A fee of 5s. is charged for the insertion of Notices of Births, Marriages, and Deaths.

# CONTRIBUTORS FOR

## SUPPLEMENTAL LIST.

THE following Physicians and Surgeons holding Honorary Hospital Appoin-  
the establishments of the Army and Navy, Medical Officers of Health, and leading  
country, have intimated their intention of contributing to the columns of THE LAN-

- ADAM, A. MERCER, M.D. Edin., Surgeon to the Boston Cottage Hos-  
pital.
- ATKINSON, E., M.R.C.S. Eng., Surgeon to the Leeds General Infirmary,  
and Lecturer on Surgery at the Leeds School of Medicine.
- BEACH, FLETCHER, M.B. Lond., M.R.C.P. Lond., M.R.C.S. Eng.,  
Medical Superintendent of the Darenth Asylum, Dartford.
- BIRD, TOM, M.R.C.S. Eng., Instructor in the Use of Anæsthetics at  
Guy's Hospital, and Administrator of Anæsthetics at the East  
London Hospital for Children and Hospital for Women, Soho-square.
- BISSHOPP, J., L.R.C.P. Lond., M.R.C.S. Eng., Surgeon to the Tun-  
bridge Wells Provident Dispensary.
- BOULTON, PERCY, M.D. Edin., M.R.C.P. Lond., Physician to the  
Samaritan Free Hospital for Out-patients at Queen Charlotte's  
Lying-in Hospital, and to the Home for Incurables, Clapham-rise.
- BRUCE, J. MITCHELL, M.D. Lond., Senior Assistant Physician and  
Lecturer on Materia Medica and Therapeutics at Charing-cross Hos-  
pital, Sub-Dean at Charing-cross Hospital Medical School, and  
Assistant Physician to the Hospital for Consumption, Brompton.
- BUZZARD, T., M.D. Lond., Physician to the National Hospital for  
Epilepsy and Paralysis, and Physician to the Artists' Annuity and  
Benevolent Funds.
- CANNING, P. W. G., L.R.C.P., L.R.C.S. Edin., Resident Surgeon at  
the Hull and Sculcoates Dispensary, Hull.
- CHARTERIS, MATTHEW, M.D. Edin., L.R.C.S. Edin., Professor of  
Materia Medica and Therapeutics at the University of Glasgow, and  
Physician and Lecturer on Clinical Medicine at the Glasgow Royal  
Infirmary.
- CRIGHTON, R. WILKIE, M.D., L.R.C.S. Edin., Physician to the  
Tavistock Dispensary.
- DALBY, W. B., M.B. Cantab., F.R.C.S. Eng., Aural Surgeon and  
Lecturer on Aural Surgery, St. George's Hospital.
- DRUMMOND, D., M.D. Dub., Lecturer on Physiology at the University  
of Durham, Physician and Pathologist to the Newcastle-on Tyne  
Infirmary, and Senior Physician to the Children's Hospital, New-  
castle-on-Tyne.
- DUNLOP, W. M., M.B. Glasg., Resident Medical Officer at St. Pancras  
Workhouse, London, N.W.
- EALLES, H., M.R.C.S. Eng., Honorary Surgeon to the Birmingham and  
Midland Eye Hospital, and Demonstrator of Anatomy at the Queen's  
College, Birmingham.

## Notes, Short Comments, and Answers to Correspondents.

*It is especially requested that early intelligence of local events having a medical interest, or which it is desirable to bring under the notice of the profession, may be sent direct to this Office.*

*All communications relating to the editorial business of the journal must be addressed "To the Editor."*

*Lectures, original articles, and reports should be written on one side only of the paper.*

*Letters, whether intended for publication or private information, must be authenticated by the names and addresses of their writers, not necessarily for publication.*

*We cannot prescribe, or recommend practitioners.*

*Local papers containing reports or news-paragraphs should be marked.*

*Letters relating to the publication, sale, and advertising departments of THE LANCET to be addressed "To the Publisher."*

## A NOVEL CLUB.

A CIRCULAR has reached us from Preston intimating the establishment of "a Cottage and Domestic Servants' Club," with a tariff of charges, signed by "A. Primrose Wells, B.A. Cambridge, L.R.C.S., L.R.C.P., &c., late Assistant House-Physician to St. George's Hospital." The circular has, we are informed, been sent to all the houses in Preston. This is strange action for a graduate of Cambridge and a late assistant house-physician at St. George's Hospital, on which Mr. Wells will not reflect with satisfaction.

## HYSTERICAL IMITATION OF THE EFFECTS OF ETHERISATION.

To the Editor of THE LANCET.

SIR,—A curious hysterical condition that came under my notice on the 30th of last month is, I think, unique.

The patient was a young lady, about eighteen years of age, and had to undergo an operation in connexion with the mouth. It was arranged that this should take place under the influence of an anæsthetic. About three years and a half ago I had administered ether to this patient, and some teeth had been extracted while she was under its influence. Hysterical laughing and crying preceded the return to sensibility, and this condition lasted for several hours. On the morning of Nov. 30th I poured some ether into a cone, which I held for a second or two about three inches from my patient's mouth, so that she might get accustomed to the smell, this being a practice I am in the habit of adopting before pressing the cone on to the face. She could have scarcely recognised the odour when I was struck by her peculiar appearance, and I therefore placed my cone upon a table that was near to me and watched the strange hysterical condition that ensued. First the eyelids quivered with great rapidity and there was a strong convergent squint, the face becoming congested and assuming that purple tint so common in the early stage of anæsthesia. Then followed violent trembling of the upper and lower limbs, succeeded by strong convulsive struggles, and lastly complete muscular flaccidity, with heavy breathing. I could now touch the edge of the upper eyelids without producing reflex action. The time occupied by these successive stages was from two to three minutes, and no ether was inhaled beyond such whiffs as might have reached the patient while the cone was three inches away from her mouth. The moment I replaced it she became sensible, and it was with considerable difficulty, and after the expenditure of seven ounces of ether, that I produced insensibility. When the operation was over violent hysterical crying came on and lasted for more than three hours.—I am, Sir, your obedient servant,

JAS. GODFREY THURPP,

Formerly Etherist, &amp;c., St. George's Hospital.

St. Stephen's road, W., Dec. 5th, 1882.

## PARISH RELIEF IN IRELAND.

WITH the view of relieving cases of distress in Ireland, which have been forwarded to the Boards of Guardians of unions, is anticipated. The Boards are advised that the powers vested in them by the existing Poor-law which need relief are cautioned not to look forward to public money on public works, but to take advantage of the present provided. The circular states that, satisfied by experience that relief works are not demoralising in their effects, but often fail to aid in order, however, that distress may be properly made that each relieving officer be directed to different parts of his district for the purpose of from persons needing relief.

F.R.C.S.—There is no vacancy in the Council of the at present. Mr. Holden, who still retains his seat to be a member of the Court of Examiners in Surgery and also of the Dental Board.

Mr. Gibbs (Darlington).—The document has passed Application might be made to the author.

Mr. Frank Edwards.—We do not know of any such

Mr. Godlee.—Next week.

## AN APPEAL.

To the Editor of THE LANCET.

SIR,—The distressing circumstances of the case bring before your readers' notice are my excuse columns; I trust they may plead with the benevolence for their practical sympathy and help. The appeal is on behalf of the three orphan children of Griffiths, of Dublin, aged respectively eight and four and a half years. Their father, who was a physician and surgeon, was author of several valuable Medical and Chemical works. Some of these were: "Posological Tables," "Materia Medica and Prescribing," &c. He also occupied the position of Royal College of Surgeons in Ireland, and Lecturer in the School of Medicine, Dublin. In his life he was the utmost satisfaction, and, owing to his kindness, he soon became a particular favourite with those brought in contact with him. In the year 1877 he was with an attack of typhoid fever, and having a violent action—never a robust one—by continued mental as severe literary work at late hours of the day, he fell a victim to the attack, and died on the fourth day of the early age of thirty-one, leaving a very delicate children in very distressed circumstances. The months after his father's death. The very week he was about to effect an insurance on his life for his family. Unfortunately, however, he completed. Two months ago his wife, who was the mother of her young family, succumbed to an attack of three little orphan boys are now wholly helpless, and receive from an aged grandmother, who supports the precarious mode of existence of letting support and educate these children till they themselves is the object of my appeal and which has just been formed. Any subscription, or to any of the following gentlemen, received and acknowledged:—Rev. F. P. O'Malley, Mount-Avenue, Leeson-park, Dublin; Rev. J. S. Herbert-place, Dublin; Walter G. Smith, Esq., Street, Dublin; Kendal M. Franks, Esq., M.D., Dublin.—I am, Sir, yours, &c.,

LAMBERT H.

4, Merrion-square West, Dublin, Dec. 20th.

M.A. Oxon.—Yes, the Mr. Arthur Smyth Flood, whose name was amongst the successful candidates for Intelligence, is the eldest son of Professor College of Surgeons.

Dr. Philip Foster (Leeds).—1. The experiment under our notice.—2. We see no objection.

M.R.C.S. (Bath) has not enclosed his card.

## "SALICYLATE OF SODA IN

To the Editor of THE LANCET.

SIR,—In your issue of the 16th inst. I have by Mr. Couldrey under the above heading several months past I have prescribed the following: scarlatina, and with the happiest of results. Forty grains of salicylic acid, half a drachm of two drachms of syrup of mulberry, and lemons to three ounces of water; one teaspoonful (a girl eight years of age), the dose to be repeated.

The subject is at present engaging my attention on the occasion to offer a communication on the subject.

December 20th, 1882.

[illegible][illegible]

## MADEIRA.

WE have received from Messrs. Butler and Son, Fenchurch-buildings, an excellent photographic view of Madeira, which will be interesting to intending visitors to that famous health resort.

*J. B. S.*—We think our correspondent was justified in expecting his fee. Cases in point have been decided in county courts, one of which was reported in THE LANCET of Jan. 25th, 1873, p. 150.

*Mr. Redmond.*—It would be impossible to comply with our correspondent's request.

COMMUNICATIONS not noticed in our present number will receive attention in our next.

COMMUNICATIONS, LETTERS, &c., have been received from—Rev. W. P. Roberts; Mr. Christopher Heath, London; Mr. Stevens, London; Dr. Hebb; Dr. Heron; Dr. J. C. Warren; Mr. Symonds; Dr. F. ## Clinical Remarks

ON A

## CASE OF BRONCHIECTASIS TREATED BY TAPPING.

By C. THEODORE WILLIAMS, MA., M.D., &C.,  
PHYSICIAN TO THE HOSPITAL FOR CONSUMPTION AND DISEASES  
OF THE CHEST, BROMPTON.

GENTLEMEN,—Bronchiectasis in its worst form is one of the most troublesome affections the physician has to deal with, and the subjoined is instructive, as indicating some of the difficulties.

Charles R—, aged forty, a baker, was admitted into Brompton Hospital on April 28th, 1882, under my care, with the following history. There was no consumption in the family; he was chilled twelve months ago, and had cough and expectoration ever since, with some pain in the chest and tightness, for which he became an inmate of the Bath United Hospital, and remained so till April, 1882. During this period he had night-sweats and more or less pyrexia, the temperature rising to 103° F., but being generally from 99° to 100° in the mornings, and 100° to 101° in the evenings.

On admission the cough was very harassing, inducing vomiting; expectoration abundant, purulent, and so fetid that the patient had to be isolated from the other patients. It contained no lung-tissue. Breath very foul. Pulse 106; temperature 99.4°; respiration somewhat hurried; weight eight stone four pounds and a half. Physical signs: Right side anteriorly hyper-resonant to upper border of the fourth rib; below marked dulness, and intercostal spaces retract on inspiration; bronchophony audible over the whole front, also coarse crepitation, replaced in certain spots by gurgle and cavernous breathing, these spots being situated in the second and third intercostal spaces, near the shoulder, and in the fourth and fifth interspaces between the nipple and shoulder. In the latter position the gurgle was audible over a spot of two inches diameter. Posteriorly, marked resonance from above to the angle of the scapula, below which was dulness with retracting intercostal spaces, as in front; crepitation audible over the whole surface, with spots of gurgling and cavernous sounds between the ninth and tenth ribs, immediately below the lower angle of the scapula, and again in another spot at the same level, two inches nearer the spine. Left side: Crepitation with wheezing sound heard over the lower half of the posterior surface. The diagnosis was chronic pneumonia of both lungs, accompanied in the case of the right by extensive bronchiectasis and adhesion of pleura. The fetor of breath and expectoration were treated by the patient wearing a Roberts' respirator containing a mixture of creasote and carbolic acid, the air of the ward was diffused with vapour of thymol or eucalyptol, the expectoration was duly deodorised by terebene, and stimulant expectorants administered, in addition to two ounces of brandy daily. Notwithstanding these measures, the cough continued sufficiently violent to cause vomiting, the expectoration was so fetid as to greatly distress the patient, and, in spite of all precautions, the smell reached the gallery and penetrated into some of the adjacent wards. After consultation with Drs. Douglas Powell and Tatham, I decided to ask Professor Marshall to make an opening into the largest bronchiectasis, and thus to secure efficient drainage.

On May 22nd Mr. Marshall made a vertical incision along a line drawn by myself, from the fourth to the sixth ribs, about two inches to the right of the right nipple. He divided the skin and laid bare two intercostal spaces, the object being to puncture the upper space, and in case of our thus failing to reach the bronchus to try the lower space without a fresh incision. Mr. Marshall then plunged a special trocar and cannula, with director attached, to the depth of four inches towards the root of the lung. Air hissed through the opening, followed by a large quantity of fetid matter, which was ejected with considerable force. Mr. Marshall then extended the opening by means of his knife and finger, and more fetid mucus, this time mixed with sloughs and

shreddy lymph, appeared; some blood also flowed. A piece of French catheter-tubing was fastened in, through which the discharge passed into antiseptic dressings.—23rd: Slept well; a fair amount of discharge runs through the tube; expectoration diminished, hardly fetid; wound looks well. Temperature 99.8°; pulse 100.—24th: Dr. Hicks found the tube to be slightly movable; discharge free and not offensive; expectoration thirteen ounces, devoid of smell, and breath tolerably pure. Two days later, the expectoration and discharge remaining about the same, the patient had diarrhoea, lasting two days, arising, it was supposed, from swallowing sputum; urine 1020, no albumen.

June 1st: The tube was changed, and the patient was allowed to walk in the grounds of the hospital. He remained fairly well; the expectoration about seven ounces daily, and the discharge tolerably sweet, till June 8th, when the discharge increased; there was a slight rise of temperature to 100°.—4th: The patient complained of headache.—12th: The sputum slightly fetid. Still headache. Discharge increased.—17th: Patient has had severe frontal headache and vomiting with much flatulency since 4 A.M. Wound the same; discharge more fetid. Temperature 101.6°. Ordered a calomel and podophyllin purge. This produced a number of motions, but no relief to the headache, which increased, and appeared to correspond with a diminution of the sputum, the quantity falling from six ounces to one ounce and a half on the 20th, and on the 24th he became drowsy, with more headache. Movement was impaired on the left side. No expectoration.—26th: Headache diminished; left pupil large. Breath very offensive. No sputum.—29th: Very drowsy. Passes motions under him. Wound the same.

July 1st: Complete hemiplegia of the left side of the body. The patient was drowsy and nearly unconscious. He died five days later; the sputum being altogether retained. The autopsy was performed on the following day. The subjoined is an abstract of Dr. Ewart's, the pathologist, and Mr. H. Williams', my clinical assistant, notes. A fistulous opening was seen in the right side of the chest between the fourth and fifth ribs, two inches to the right of the nipple line. The right pleura was universally adherent, rather closely so, by means of a strong fibrous tissue. The right lung was deeply congested and practically devoid of air; the tissue was collapsed, sodden, congested, and infiltrated with pus. A more or less uniform dilatation of all the small bronchi was noticeable on close inspection. Sacculular dilatations as large as peas or almonds existed in the thickness of the basic fringe from sternum to vertebrae, but the main disease was situated in the lower part of the upper lobe anteriorly, and in the anterior portion of the lower lobe. The greater part of the sternal portion of the upper lobe was converted into a 'baggy' multilocular saccululation with thin but very tough fibrous walls, and containing some fetid fluid. This cavity, which was typically bronchiectatic, was also of the size of an orange, and communicated by an artificial channel with the fistulous opening on the chest wall, showing that the principal dilatation had been successfully tapped. In the sternal portion of the lower lobe the saccululations were much smaller, but very numerous and separated by a tissue thoroughly soaked in purulent fluid. The posterior parts of the lung were comparatively free from disease with the exception of two inches and a half above the diaphragm in the interscapular region, where a series of small sacculations about the size of a walnut was found. The left lung had no pleural adhesions, and was crepitant throughout, and tolerably healthy. No bronchiectases were detected in it. The bronchial glands beneath the bifurcation of the trachea were enlarged, pigmented, and soft. No tubercular or caseous deposits were found in either lung. The brain weighed fifty-five ounces, and in the right hemisphere was discovered a cyst as large as a Tangerine orange with walls varying in thickness from one-eighth to one-sixth of an inch containing pus. No abscesses were discovered in the other organs, which were carefully examined and found quite normal.

This case exemplifies some of the difficulties we have to encounter in the treatment of bronchiectasis. The diagnosis was based on the position of the physical signs, especially of the spots of gurgle, which are generally peculiar to bronchiectasis, and on the character of the expectoration; and it was proved by the autopsy to have been fairly correct. It must be admitted that much aid was derived from the fact of the cavernous sounds being very localised and apparently superficial. We had not to deal with a labyrinthine series of dilatations, as in a case com-

c c

communicated by me to the Clinical Society in 1879, where cavernous sounds were audible over a far larger surface than the size of the cavity, owing to its peculiar form. The entire failure of antiseptic inhalations, the knowledge of an adherent pleura, and the certainty of speedy death from septicaemia, induced me to have recourse to the operation, with the immediate results of which I was quite satisfied. I would specially draw attention to the advantage of making an incision, as Mr. Marshall did, over two intercostal spaces in cases where the area of gurgle extends as far; so that, if puncture in the first space fails, we can try the one below or above, as the case may be, without fresh incisions. Another point is using Dr. Hicks' admirable combination of trocar, cannula, and director,<sup>1</sup> so that the channel into the cavity may not be lost through accident—a by no means infrequent occurrence,—but gradually enlarged with the knife, and a large drainage-tube introduced. The wonderful improvement in the cough, the diminution of the expectoration, and disappearance of fetor, indicated in this case, as in Dr. Douglas Powell's case recorded in the 63rd volume of the Medico-Chirurgical Transactions, that much of the expectoration was due to the irritation set up in the bronchi by the passage of fetid secretion; and the marked amelioration made us hope that we were getting over our difficulties. But the return of fetor, the diminution of the expectoration, and, lastly, the pain in the head, followed by hemiplegia, showed clearly that absorption of matter and pyæmia had set in. The presence of an abscess in the brain and the total absence of any other abscesses in other organs were remarkable, and made one doubt at first if the brain abscess were pyæmic, but the curious relation between the diminution of expectoration and the increase of pain in the head certainly pointed to a pyæmic origin. The expediency of operating at all in these cases must be judged of by considering their probable termination. Some patients appear to gain expectorating power by using antiseptic expectorants in the form of medicines as inhalations, and are enabled to empty their bronchi sufficiently to prevent large and fetid accumulations. In others one of four events happens: (1) Either some of the fetid secretion passes during the movements of respiration into adjoining bronchi, or into the main bronchus of the opposite lung, and gives rise to septic pneumonia and death; (2) or the fetid products are absorbed by the lymphatics and bloodvessels, and give rise to pyæmic abscesses in some part of the body, as in the present case; (3) or, again, the bronchiectasis may burst into the pleura and cause pneumothorax; (4) or, lastly, the patient may die of suffocative bronchitis from the secretion penetrating into all or the greater part of the alveoli. All these four terminations are fatal in a shorter or longer period, and it is to obviate them that operations are undertaken. Taking the forms of bronchiectasis into account, of the two cylindrical and globular, the globular form of dilatation of the bronchi is the worst to treat, because all tonicity of the walls appears to have been entirely lost, and although we may tap and relieve one of these collections of fetid pus, we never can be quite sure that another one does not exist in another part of the lung, so that not one but many operations are required, and it looks sometimes as if there was more probability of our reaching the end of the patient's life than of the end of the operations. In the three other cases of bronchiectasis on which I have had operations performed, in all more than one operation was performed. In one six openings, in another three, were made, and this last patient stood the operations well, and is still living, a year and a half after. In the present case we were fortunate enough to hit the largest of the bronchiectases, and I hoped, as it was the lowest, that it would carry out sufficient drainage of a large portion of the bronchial tree. The question may be asked why I did not have another operation performed, but we had no indications. The opening was not blocked, but patent, and the septic symptoms came on too rapidly to allow of more apertures being made.

<sup>1</sup> Lately exhibited at the Medical Society of London.

At a recent meeting of the guardians of the Wandsworth and Clapham Union, Dr. Longstaff, in moving that the whole question of the accommodation provided in the infirmary and the new workhouse be referred to a committee, is reported to have stated that the infirmary was so overcrowded that some of the inmates had to sleep on the floor and in the kitchen.

## ON SPINA BIFIDA.

By G. B. BARRON, M.D., M.R.

THE subject of spina bifida has been discussed in the columns of THE LANCET, and an unusual interest has been evinced in its radical cure by methods of treatment. How far all cases can be amenable to any treatment, or how far justifiable to attempt so dangerous an experiment injecting a cyst of this character, is yet beyond of our knowledge. The cases of successful cure are too limited to warrant any inconsiderate rash and heroic step as rushing in with some hope of success to stop the gap Nature in her has omitted to close. The following case is to record as illustrating how tolerant the human system may be of unnatural processes, and how new ideas may remain unaffected, contrary to our ideas of their integrity. The literature of the subject is unsatisfactory, as authors, in treating of the subject, have it over in a brief and rather off-hand manner. An article on the disease is to be found in Cooper's Dictionary. Cooper relates some interesting cases, but his scientific lines of treatment whereon confidence are even here wanting. I apprehend that surgeons are divided in their opinions as to the best method of dealing with it, and none yet dare issue a definite opinion of probable successful operation. Cooper relates a case which was cured by repeated tapplings and punctures, but states in other cases these measures failed and death ensued. He also says, "We must regard all attempts to cure the disorder by making any kind of opening as being extremely dangerous, and generally fatal." Bryant doubts. He says, "Almost all these cases prove fatal. Many of the subjects are ill-developed, within a few days of birth; some die in childhood, and this mode of death is very usual when the child and its fluid contents escape." Then, as to treatment, he goes on to say: "Palliative treatment is all that is allowed in the majority of cases, although in some instances operative interference promises to be successful. Holmes somewhat favours injection of the cyst, but his practice is almost only adapted to small pedunculated cysts. Erichsen relates a case with an enormously large cyst which was successfully treated by tapping. Probst relates a case which has no parallel in surgical literature. He concludes, "We shall probably best consult the interests of the child by abstaining from all operative interference, and does not even allude to injection."

The cases related at the Clinical Society, and the subsequent discussion, prompt the inference that surgeons are present most disposed to rely upon injection of the cyst. Still, the meagre success and the paucity of cases scarcely justify reliance upon that method. Here we have a case which surgical science requires to deal with without resort to any of these methods.

Three years ago, being on a visit in Worcestershire, I was requested to see the child of a farm labourer living in an adjacent village. The child, well nourished and looking, was six weeks old, and was the subject of spina bifida, situated between the fourth and fifth lumbar vertebrae. It was the size of a small hen's egg. Mr. Woodward, of Pershore, had attended the case, and was present at the time I saw it. The skin looked shiny and red, and was ready to give way. I advised aspiration or tapping, but the latter procedure was adopted by a large hypodermic needle, which was left in the sac for a few hours. About eight drachms of fluid were withdrawn. A piece of cotton-wool was applied to protect the part, and the child was cautioned not to handle the child roughly, and to avoid undue pressure on the swelling.

By the courtesy of Mr. Woodward, in August last I had an opportunity of seeing the child again, and notes of its condition, taken at the time, run as follows: The child is fairly well nourished, and is about the size and weight of a three-year-old child, and has the appearance of full health. It can walk, but its gait is a little hunched and slightly "straddling," with its feet rather more than natural, as though it had a difficulty to secure equilibrium; the lower extremities are thin, but the hands are means emaciated, and sensation is perfect, the

being intact, and plantar titillation immediately as the usual muscular jerk. There is perfect control of the sphincters, and the urine is voided in a full stream. There is no lack of intelligence, the eyes are full of expression, the head of normal size and shape, with no sign of hydrocephalus. Pressure on the tumour produces no symptom of distress, nor does it alter materially the size of the aperture. It has a very broad base, and the edges of the aperture can be felt, the finger-tip detecting a large circular ovoid opening communicating with the spinal cavity. The size of its base indicates its non-pedunculated character. The measurement in circumference at base is fifteen inches, and across from side to side eleven inches. It is as transparent as a hydrocele. The case, when first I did not encourage the idea of attempting a cure by tapping, and I may mention that it has been tapped frequently, but has rapidly refilled each time.

The curious and interesting points about this case of hydromyelia seem to me to be these: the size of the tumour; the full development of the lower extremities; the rapidity of progression; the absence of pressure on the spinal cord, and thus the sphincter integrity. While the size of the opening would point to the possible pressure on the spinal cord, if broad based tumours are more likely to press upon the spinal cord than pedunculated ones, how is it there is no evidence of pressure here? Suppose the nerve structures are pushed forward in front of the fluid, I think we might reasonably on physiological grounds expect to find evidence of nerve pressure, or malnutrition from nerve stretching, or nerve atrophy. There is no talipes in this case. We have told not to puncture the front part of these tumours so as to injure the nerves, but is there any evidence that the structure of nerve structure in this part of the body by a fine needle has been productive of permanent mischief? This seems to me, if not unique, at least curious and demands the following considerations.

If the subarachnoid fluid both of the brain and spinal canal normally does not exceed two ounces, how is it that this tumour is so large? We know the fluid is reproduced rapidly when withdrawn, and the withdrawal when complete produces symptoms analogous to plethora of the blood-vessels, and when it is in excess it also produces convulsions and other evidences of pressure. There being direct communication between the spinal subarachnoid channel, and the cerebral ventricles, how is it that when the fluid was all withdrawn in this case no convulsions ensued? and this procedure has been observed several times without mishap. As this part of the enveloping sac membrane from its internal area alone secrete the fluid, or does the whole arachnoid surface contribute its proportion? and if so why in this case above normality? The question may also be prompted, Why is there usually talipes in these cases? Is that condition purely accidental or is it due to defective tissue growth dependent upon the neural abnormality cutting off nerve-supply to a given set of muscles? I confess my inability to suggest any other method of treating, radically, hydromyelia; but, except in the matter of injection, we have made no advance in our knowledge of it during the last fifty years. This is a reproach to our modern surgery, which boasts, and with perfect justice, of feats so brilliant that they become almost incredible as compared with the surgery of the past half century. Of this I am quite convinced, that something will be won upon the intellect, as a more certain and effective means of dealing with this disease. An interest has sprung up which will eventuate in some satisfactory operation. Can we in any way imitate sloughing which produces spontaneous cure? To say that hydromyelia is an incurable disease would be considered unsurgical, but I am by no means convinced that some better method may not yet be discovered than we at present adopt. The old plan of a seton must be condemned, so I think must tapping and pressure, experience teaching that no reliable good ensues from these measures. It is to be hoped every successful case of cure by injection, no matter what the agent used may be, will be published, that tabulated results may lay the foundation of something like a sound basis whereon to act, and which will inspire confidence in dealing with this *bête noire* of surgery.

Southport.

## CASE OF FEIGNED SKIN DISEASE.

By T. COLCOTT FOX, M.B. LOND.

A. S—, aged nearly sixteen years, a furtive-looking general servant in London, presented herself at the Skin Department of the North-West London Hospital on the 28th of November. The catamenia commenced at the age of thirteen, but had since been irregular, and for the past year absent. She was fairly well nourished, but pasty-looking, and her finger-nails were markedly grooved. She applied on account of three excoriated patches which appeared on Nov. 21st, close together on the front of her left leg, and had, she stated, given her great pain, and caused her to lie awake sobbing at night, so that her mistress had no longer the heart to keep her at work. The suggestion had been made that the sores were caused by the dye from her black stockings, and the girl said that she had dressed the places with "Moore's ointment." One sore was perfectly oval, another nearly heart-shaped, and the third triangular, with a horn at each angle at the base. The patches measured about 1½ in. by 1½ in. to 2 in., and the long axis was in the direction of the limb; they were simple uniform weeping excoriations, with hardly any attendant inflammation. Suspecting the nature of the lesion, I ordered a simple dressing and a saline aperient, and talked of admitting the girl into the hospital if more sores appeared. On Dec. 5th she returned with a transversely oval sore just above each mamma (a very characteristic site in feigned cases, but not quite symmetrically situated. There were two others above the left ankle-joint, and one on the outside of the right calf, all longitudinally oval simple excoriations, with a well-defined border, except on one sore, where the abrasion was not complete at one end, and only papulation existed, suggesting a cantharides application. There was a dark-brown blood scab on some. She was admitted to the wards. On Dec. 6th a transversely oval patch appeared just below the left mamma; and another, longitudinally oval, covered with a slight scab, on the right hip. The girl from time to time, for twenty-four hours after admission, had prolonged fits of hysterical sobbing. On the 12th a sore appeared on the right shin near the ankle, and another on the right mamma, between the site of a former excoriation and the areola. There was a remarkable uniformity in the size of the patches throughout. As to the agency at work, I never could detect any evidence of the formation of a bulla, and the patches were too superficial for causation by an acid; moreover, repeated examination of the clothes, bedding, &c., at convenient times and unbeknown to the patient, failed to furnish any clue. On the 16th, no more excoriations having appeared, I taxed the girl with producing the eruption artificially, and, after prolonged denials, she confessed that she had done so, partly by her nails, but mostly by continued rubbing with the tops of her fingers. Probably the malingering was not altogether motiveless, and she desired a rest from her household labours. She proved to be very troublesome and disobedient in the ward, and I learnt from her father that she was an incorrigibly bad girl and a constant source of worry. The case is of interest as establishing an agency which has hitherto only been suspected as possible. Whether the skin in these cases is peculiarly sensitive to injury is a point for further investigation.

Harley-street.

## LARGE ASYLUMS FOR THE INSANE.

By H. RAYNER, M.D.,

SUPERINTENDENT OF THE MALE DEPARTMENT OF THE HANWELL COUNTY ASYLUM.

It appears to me to be desirable to draw attention to a danger which threatens the welfare of the insane poor of England and Wales. This danger arises from the conversion of asylums of a size that is efficient and economic, into larger asylums that are less economic, and I fear less efficient. Moreover, valuable opportunities are being lost by the building of large, cheap asylums for the detention of lunatics, in place of efficient hospitals for their treatment

c c 2

On Wednesday morning Dr. Edwardes, of Hounslow, was found dead in his chair. It is stated that there was evidence present of death having been caused by prussic acid.

and cure. These errors are being committed from the prevalent belief that large asylums are the cheapest.

The following figures abstracted from reports prepared for other objects will, I hope, tend to correct this mistake, and prevent further mischievous consequences. The thirty-sixth Report of the Commissioners in Lunacy for the year 1881 yields the following statistics in regard to the English county asylums. (The borough asylums are excluded as being under different conditions.) The asylums I have divided according to their number of inmates into four groups: the first, in which there are less than 450, being considered too small; the second, above 450 and under 600, being taken as the most favourable size for economy and treatment; and the two other divisions being made only to show the increase of cost with the increase of size.

Names of Asylums.	Number of beds.	Average weekly cost per patient.	Number of patients to each medical officer.
Northumberland, Notts, Derby, Cumberland, Berks, Bucks, Cambridge, East Riding, Hereford, Denbigh, Suffolk.	Less than 450 beds	s. d. 9 7½	181
Dorset, Oxford, Salop, West Riding, Cornwall, Wilts, Chester, Monmouth, Burntwood, Leicester, Carmarthen, Glamorgan, Northampton.	450 to 600 beds	8 10½	223
Lincoln, Norfolk, Sussex, Parkside, Warwick, Hants, Stafford, Rainhill, Devon, Gloucester, Chatham, Somerset, Worcester.	600 to 800 beds	9 3½	265
Beds, Durham, Whittingham, Essex, Wandsworth, Brookwood, Lancaster, Wadale, Prestwich, Wakefield, Banstead, Hanwell, Colney Hatch, Barming Heath.	Upwards of 800 beds	9 5½	345

This table shows, as might be expected, that those asylums are dearest which are not sufficiently large to justify the necessarily complex and expensive staff of such institutions; and it also shows that beyond this is a class much more economic, and, if judged by the proportion of medical attendance supplied, much more efficient than the larger asylums.

A Parliamentary return for the year 1877 yields the following statistics:—

Names of Asylums.	Size.	Total number of beds.	Total cost.	Average cost per bed.
Northumberland, Notts, Derby, Cumberland, Oxford, Berks, East Riding, Suffolk, Denbigh, Cambridge, Carmarthen, Hereford.	Not more than 450 beds	4580	£ 785,570	£ 171·5
Northampton, Burntwood, Bucks, Glamorgan, Cornwall, Dorset, Monmouth, Stafford, Salop, North Riding, Chester, Wilts.	450 to 600 beds	6307	963,122	152·7
Gloucester, Hants, Devon, Worcester, Beds, Essex, Lincoln, Parkside, Rainhill, Somerset.	600 to 800 beds	7099	1,303,166	183·5
Barming Heath, Wandsworth, Hanwell, Colney Hatch, Lancaster, Durham, Whittingham, Brookwood, Wadale, Prestwich, Wakefield, Banstead.	800 beds and upwards	16,423	3,215,717	196·9
Banstead (Asylum for Chronic Cases).	—	1700	276,422	162·9

This report includes all the county asylums of which the returns were available, and shows that the asylums of from 450 to 600 beds are the most economic in construction, larger asylums being dearer in proportion to their size; even

Banstead, constructed in the simplest manner, view to cheapness, being more costly.

A second Parliamentary return for the that in—

#### Asylums of

Not more than 450 beds	.....
450 to 600	.....
600 to 800	.....
Upwards of 800	.....

In this respect the cost would seem to be to the increase of size.

Statistics are proverbially unreliable, considered these carefully, from other points here, with the result that, making a consider the above figures to approximate truth. Assuming that they do so, we following summary of results, in comparison asylums (450 to 600 beds) with the 1 beds and upwards). In the large as 6½d. more per week, and each bed of construction and £1·06 annually in repair to saying that if 40,000 patients (and this is close upon this) were lodged in large cost £1,760,000 in construction of bulk in repairs, and nearly £60,000 annually more than the same number in a advocate.

The current economy is of small importance in the question of efficiency, and this extent on the personal influence of a patient, an influence which I believe a junior officer, however efficient and

The primary importance of the physician was emphatically expressed, and was fully recognised by the Commission their report for 1857, in which they very large buildings on account of the responsible supervision, the loss of time and the tendency of the rate of mortality. I could quote many other authorities in opinion, but that I might appear to

Then arises the question, Over what can an average superintendent exercise personal influence, and at the same time control over the asylum that every patient be used to the greatest advantage for I answer that the number should be that the balance of advantage lies in the number than this.

I do not doubt that efficiency in the larger asylums, but, as the price is much greater cost, which must be the number of medical supervision proportionate to that in the medium

Believing as I do that the current almost direct ratio to the care being expressing an emphatic protest against asylums of useful size, or the large repositories in place of lunatic hospitals at Hanwell.

#### TWO CASES

#### INTRA-VEIN INJECTION FOR SEVERE HÆMORRHOID

BY WM. COATES

RESIDENT ACCOUCHEUR, LATE HOUSE

PROMINENCE having lately been brought to the subject of intra-venous combating the effects of severe hæmorrhoids with which Mr. Jennings has been afflicted, I wish to supplement what has been the history of two cases in which the operation, both of them cases of hæmorrhoids, that the hæmorrhoids occurred a long time after the cause, and that they were the result of the Jennings's syphon has been employed.

The first case is that of Emily C—, aged twenty-six, a patient of the London Hospital Maternity Charity. She is a married woman, has had five children, but has always been delicate. Has had heart disease for some years, having hadumatic fever when young. On October 16th she was seen in labour early in the morning, and at 1 P.M. I was summoned to the case. The patient was feeble, pulse rapid and intermittent, and she had stenosis and incompetence of mitral valve. The head was low in the pelvis, in the second position, but as the pains were few and there had been no further descent during the last three hours, delivery was effected with Barnes' long forceps, and the placenta easily expressed. About twenty minutes after delivery violent hæmorrhage occurred. Manipulation, hypodermic injection of sclerotic acid, cold affusions, ice internally and externally, the intra-uterine injection of hot water, were all resorted to; but these measures failing to produce more than a temporary uterine contraction, ten ounces of a solution of perchloride of iron (one in five) were injected into the uterus. The hæmorrhage ceased, and after the lapse of a little time the uterus contracted moderately. The patient progressed favourably, and seemed in a fair way towards recovery, when, contrary to instructions, she sat up for an hour on November 1st, and again began to flood. She was found in an anæmic and weak state, but the hæmorrhage was easily arrested. Two days afterwards the bleeding returned, and the friends did not summon assistance until she had been "losing" for eight hours. When seen the bed was saturated with blood, and the patient appeared almost moribund. Pulse was only just perceptible at the wrist, and very frequent; skin and mucous membranes were almost bloodless, extremities and face were icy cold, vision was dim, she did not recognise any one about her, and was seemingly unconscious. Although apparently quite still, her friends stated that she had been tossing violently. My colleague, Dr. Basil Walker, agreeing with me as to the necessity for immediate action, and the husband being unwilling to supply blood, Jennings' syphon was procured, and the saline alcoholic solution recommended by me (THE LANCET, September 16th), and which is almost identical with that suggested by Mr. Little in the London Hospital Reports (1866) was allowed to flow into the radial vein, this being the only visible one and of fair size. The result was marvellous. Sight and consciousness returned, the pulse gradually but steadily improved, the patient expressed herself as feeling "beautiful," and soon was able to retain stimulants, which were freely administered. She died a good night, seemed better in the morning though extremely anæmic and weak, and the possibility of another outburst of hæmorrhage being entertained, she was brought to the hospital. With the exception that symptoms of acute mania appeared on November 17th her progress has been most favourable, and recovery is probably not very remote. To give some idea of the intensity of the anæmia it may be stated that retinal hæmorrhages have been observed in both fundi.

The next case is that of Mary C—, aged twenty-seven, patient of the same Charity. On November 10th she was confined of a healthy child after an easy labour. Her convalescence apparently proceeded rapidly. She sat up on the fifth day and performed household duties in a week. On the 19th, soon after straining at stool, she became faint, and then flooded alarmingly. At 1 P.M., half an hour after the onset of the hæmorrhage, the appearance of the patient denoted severe loss of blood, which was found in large quantity upon the floor and bed. The uterus was relaxed, and blood was flowing in gushes from the vagina. The os was not admitted a finger, and the uterus was full of clots. Sclerotic acid, ice, kneading, &c., failing to arrest the hæmorrhage, the vagina was plugged, and patient brought to the hospital. When seen soon after arrival—2.30 P.M.—she appeared much worse, was vomiting, and complaining of abdominal pain. A large tumour was felt, reaching almost to the ensiform cartilage, which proved to be the uterus distended with blood, the constricted os evidently preventing its free exit. A digital exploration of the uterine cavity was now made—the large uterus and small os rendering this incomplete; but nothing abnormal, except a little softening of the anterior wall, could be detected. Failing to check the bleeding, and wishing to ascertain its origin, the os was somewhat rapidly dilated with Barnes' hydrostatic bags. By this time, however, the state of the patient had become most critical. She said her sight was dim, and that she must die. The pulse was almost imperceptible; respiration was irregular; extremities cold; and there

was jaundition. Mr. Unsworth, house-surgeon, concurring with me that there was no time to be lost, and no vein being visible, an incision was made over the situation of the median cephalic, and that vein exposed, into which about twenty-two ounces of simply warm water, at a temperature of about 100° F., were injected with the aid of Jennings' syphon. The result was no less striking than in the preceding case. The pulse became regular, ceased to intermit, and its volume increased; respiration improved; sight returned; and the uterus slowly but distinctly contracted; she at the same time expressing herself as feeling better. At about 4.30 P.M. Dr. Herman saw the patient, and, the os being now fairly dilated, the interior of the uterus was examined, but nothing further was discovered to explain the flooding. As there was still considerable bleeding, the uterus was swabbed out with a saturated solution of perchloride of iron, diluted with about equal bulk of water, and the patient was removed to bed. An enema of beef-tea and three ounces of brandy was administered; but in a short time she could swallow, and stimulants were freely exhibited. The patient is now progressing uninterruptedly towards convalescence, not having had a bad symptom, except a slight elevation of temperature (102° F.) the first few days.

I have pleasure in bearing testimony to the general efficiency of Mr. Jennings' instrument, and although on these occasions I was materially assisted by my colleagues mentioned and Mr. C. J. Dabbs, I believe the operation could have been accomplished single-handed. One merit of the instrument seems to me to be that although the tube is very long, the fear of introducing air is reduced to a minimum by the situation of the hole in the cannula and by the arrangement of the stopcock and glass-interrupter. The fault that was noticed in it on these occasions—but this is one that can easily be remedied—was the sharp point of the cannula. As at present constructed, unless the greatest care were observed, not only would the point injure the wall of the vein, but it would penetrate through the whole thickness of the skin. It is needless to say that Jennings' syphon is altogether unsuitable for the injection of blood, and I believe it is not intended for that purpose, for although the blood be most carefully whipped, its passage through so long a tube would be almost certain to ensure the formation of coagula. As Mr. Jennings' elaborate instrument is not in the hands of every practitioner, it may be as well to point out that the same result might be attained by the use of an ordinary irrigating can, or even a piece of drainage-tube might be utilised to serve the same purpose—i.e., if a suitable cannula were first obtained to introduce into the vein, and this could be prepared out of a piece of marrow glass tubing.

It may appear strange that in the second case simply warm water was injected with a view of reviving the patient, but thinking that the great factor in bringing about reaction in these cases of collapse was by the introduction of some fluid into the circulatory system upon which the heart could contract, I determined to give water a trial. The result speaks for itself. The resuscitation was no less marked in this case than in the one where alcohol and saline salts were employed in addition to the water. The omission of the saline salts in no way interfered with the success, and so a fluid of a different specific gravity, and one which is supposed physiologically to swell up the red globules and cause them to yield their pigment, was injected into the blood, and with a beneficial result. It may incidentally be mentioned that when microscopically examined, twenty-four hours afterwards, there was no obvious alteration in the appearance of the corpuscles. I am prepared to admit that if the fluid injected, in addition to increasing "the dynamic force of the circulation," combined with this the property of cardiac stimulation, it must be superior, but I am inclined to attribute the good effects of the injection far more to the former than to the latter cause; and with the return of consciousness and the renewal of the circulation, stimulants may be freely exhibited which previously are either unable to be retained or else, on account of the feeble circulation, cannot be assimilated.

The outburst of secondary hæmorrhage so long after delivery adds to these cases an especial interest, which is enhanced by the obscurity of its origin. If, as I am under the impression, having seen certain suspicious-looking sloughs about the os whilst plugging the vagina, the hæmorrhage in the first case was the consequence of the separation of a slough formed after the use of the iron injection, in addition to the dangers which are attributed to the intra-uterine injection of perchloride of iron, we are confronted

by one which I fail to find alluded to in the ordinary text-books, and one which, though more ulterior in its appearance, is certainly not less fatal in its consequences. And naturally the question arises, Would the intra-venous injection have made the uterus contract as effectually as the perchloride of iron if it had been employed in the first instance? If it could be proved that such a performance would sufficiently reanimate the patient to bring about uterine contraction, then that course ought to be adopted; because, now that intra-venous injection has been reduced to a practical operation, the dangers of the latter appear diminished when compared with the former. But the issue of the second case shows that although the uterus does contract after intra-venous injection, it does not always do so sufficiently to arrest all hæmorrhage, as the perchloride had subsequently to be applied to completely arrest the flow. It may be thought that the hæmorrhage was the result of polypus, retained placenta, or other cause; but, although carefully sought for, no evidence of such was found. Getting up too soon was the probable cause of the hæmorrhage in the other case.

I am aware that final conclusions cannot be drawn from what may be called two isolated cases; but one thing, at least, appears to have been established—viz., that the operation of intra-venous injection is a practicable one.

In conclusion, I would thank Dr. Herman for his courtesy in allowing me to publish these cases.

London Hospital.

#### A CASE OF ANEURISM OF THE AORTA RUPTURING INTO THE PERICARDIUM.

By H. C. GUINNESS, SURGEON-MAJOR, A.M.D.,  
IN MEDICAL CHARGE, STATION HOSPITAL, WESTERN HEIGHTS, DOVER.

CORPORAL A. D—, Royal Irish Rifles (83rd), age twenty-three, service five years (no history of syphilis, alcoholism, or rheumatism) was admitted into Station Hospital, Western Heights, Dover, on October 24th last, with inflammation of external meatus. In spite of the treatment employed the pus became very fetid, showing its neighbourhood to bone, and there was considerable constitutional disturbance with high temperature, &c. He became low and weak, requiring stimulants, &c., but no delirium or head symptoms occurred. During his life he had no symptom to direct attention to the heart or great vessels, and there was no suspicion of the existence of an aneurism. On November 12th, about 2 P.M., after his ear was syringed, he fell back in bed and expired almost immediately. As will be seen by the post-mortem report, the case is one of exceptional interest, owing to the mischief caused by the aural inflammation, the plugging of the lateral sinus and jugular vein, and the probability of this being the cause of the rupture of the aneurism by the increased pressure on its coats, also by the very small size of the aneurism. The post-mortem report I send in full, as furnished by Surgeon Skinner, Army Medical Department.

*Necropsy.*—Body pale and emaciated, rigor mortis well marked. On removing the skull-cap, the dura mater was found to be unusually adherent to the structures beneath, just above the torcular herophili. The left lateral, petrosal, and cavernous sinuses were filled with ante-mortem clot; also the jugular vein in the jugular fossa, and for about an inch below that point. The brain substance was firm; but presented nothing unusual on examination beyond general emptiness of the veins. The left auditory meatus contained pus; it communicated with the jugular fossa by a perforation. On opening the chest, the pericardium was observed to be distended to its fullest extent by a dark substance. On opening it, some reddish fluid—in amount about two ounces—escaped, and the heart was found surrounded by a firm dark-coloured clot, which on removal weighed ten ounces. This clot was found to be especially adherent to the anterior surface of the first portion of the aorta; on removing it from this situation, a small aneurism was found rather larger than a hazel nut, with a perforation in its centre admitting a medium-sized bristle. The heart had a considerable quantity of fat externally and was firmly contracted. Its muscular structure was pale on section. The valves were healthy, but all the orifices were rather small.

The aorta presented commencing atheromatousness throughout its whole thoracic portion; the aneurism was small, with a ragged margin stained for about one-eighth of an inch, quarter of an inch in its transverse, and a one-eighth of an inch in its vertical measure. The aneurism contained some laminated fibrin. The external coat was thickened in this situation at the point of perforation, which, from the presented a funneled appearance. The lungs were somewhat congested, especially at the base. The liver was slightly enlarged and congested, but was apparently normal, also the spleen.

*Remarks.*—The post-mortem appears to confirm the opinion that the rupture of the aneurism was due to the increased pressure caused by the thrombus in the left side of the brain.

### Medical Society

#### PATHOLOGICAL SOCIETY

*Casts made with New Material.*—Diffuse Large Polypus of Rectum.—Polypus of Liver of Kangaroo.—Abscesses in Liver of Kangaroo.—A Python.—Changes in the Nerve after Atrophy.—Changes in Nerves after Atrophy and Softening of Bones in Disease without Bronzing.—Bone in Syphilis.—Micro-organisms in Pyæmia.

THE ordinary meeting of this Society was held on the 19th inst., the President, Dr. Wilks, in the chair. Dr. Goodhart's specimens of extraordinary softening of the cranial bones were received by the Committee. Dr. Lees showed a living papulatum in a boy aged three years.

Mr. BOWLBY showed some excellent Skin Eruptions made from a new material of which was described in the *British Medical Journal* some short time ago. The most important characteristics of the specimens; some of which had been made nearly a year, but possibly advantageous to add some preservative colouring of the skin eruption was described. His second specimen was a girl, aged sixty years, with diffuse Polypoid growth of the alimentary canal, and no other disease of the alimentary canal, and no symptoms during life. The growth was situated beyond the ileo-cæcal valve as half way down the descending colon and some pedunculated. They covered the mucous membrane, and had no relation to the circumference of the bowels. The patient was a girl, aged twenty, who showed a very large Fibro-cellular tumour. The patient was a girl, aged twenty, who showed the discovery of the tumour had felt occasional constipation. While sitting down something came down which she was told by Mr. Everley Taylor, of Scarborough, found a large mass, the size of a foot, protruding from the anus. The tumour was removed, and was found to be very succulent, and it was cut into, and its weight was found to be 1 lb. 10 oz. Its attachment was to the anterior wall of the rectum, and it contained very loose fibrillar tissue containing a large amount of fluid—i.e., a soft fibroma. The patient was normal. It is now ten months since it was removed, and there has been no recurrence. The absence of symptoms, were the most remarkable features. His fourth specimen was a Polypus of the rectum. A female, aged thirteen months, who was taken ill, with diarrhoea, on April 28th. She was admitted into St. James's Hospital on May 10th, and died on May 13th. The appendix was found hanging loose from the 13th a large portion of the gut was found immediately began to recover, and she was discharged from the hospital on the 19th with a good recovery. On June 1st it was readmitted.

ital syphilitic rash, and it died from marasmus on ly 2nd, without any symptoms of intestinal obstruction. Post-mortem, there was evidence of old peritonitis and adhesions of the coils together, and also to the enlarged mesenteric glands. The upper part of the small intestine was healthy. There was a polypus about eight inches from the anus, with ulceration of the gut above it. There was no colon, but there were signs of the restitution of the continuity of the canal, three inches and a half from the anus. There was very little constriction; but the tube above was dilated. The peritoneum was scarred and thickened. The polypus was doubtless the cause of the intussusception; but it was unusual for the polypus not to come away.—Dr. COUPLAND alluded to a case something like Mr. Bowlby's that was under his care two years ago, the details of which were published in the Clinical Society's transactions. The patient was twenty years of age, and a dominal section was performed for irreducible intussusception. The polypus was in the small intestine, and produced the intussusception which came through the ileo-caecal valve. Alluding to Mr. Bowlby's case of multiple polypi, he said there was a specimen somewhat similar in the Middlesex Hospital Museum.—Mr. CRIPPS remarked on the large size of the rectal polypus; and with regard to the disseminated polypi, said there were only four cases recorded in the Transactions of the several Societies and in the museums. One specimen that Dr. Coupland had alluded to was taken from a man whose symptoms dated from an attack of cholera, and he died six months afterwards. There was another specimen in Guy's Hospital Museum where there were about twenty polypi in the last twenty inches of the colon with long, slender pedicles. He had shown a specimen himself last year. There were two kinds of polypi: (1) Those formerly called villous tumours, which consisted of hypertrophy of the mucous membrane, with new epithelial layers over the retiform tissue; (2) deposit in the submucous tissue of a mass of cells, the pedicle being formed subsequently, analogous to the fibrous molluscum of the skin. He saw Mr. Bowlby's case of intussusception during life, and asked how it was that the small intestine, which must have come down through the ileo-caecal valve, did not become so slough.—Dr. WILKS thought from his experience that polypi generally occurred in little boys.—Mr. MORRIS was surprised to hear polypi spoken of as rare. He recollected seeing several cases shown in one evening at this Society, all from young children. He once operated on a woman who had polypus, fistula, and hæmorrhoids, and related a case of a man who complained of tenesmus and spasm of the sphincter, and on examination six or eight polypi could be felt in the rectum.—Dr. GOODHART said that he had met with three kinds of polypi in the museum of the College of Surgeons:—1. Like the large specimen shown to-night, which was like Mr. Curling's case. 2. The polypi of young children, which consist of mucous membrane, and are papillomatous. 3. Villous, like Mr. Henry Smith's case, where twenty or thirty were removed by the finger, but recurred. With regard to the intussusception, he thought that the colon usually sloughs, and leaves the small intestine behind.—Mr. BOWLBY, in his reply, said that disseminated polypi were usually mucous. The interest of his case lay in the fact that his had a fibrous consistence. He thought that the ileo-caecal valve in the intussusception case, as well as a part of the small intestine, had sloughed away.

Mr. J. B. SUTTON showed, first, the Liver of a Kangaroo, with about 200 small abscesses, some projecting above the surface and some deeply imbedded. All of them had caseous walls. One had burst into the peritoneum and killed the animal. He had often seen similar abscesses in birds. Secondly, he related the case of a Large Abscess occurring in the Abdominal Wall of a Python, seven feet long and five inches in circumference, which died four days after admission into the Zoological Gardens. The cavity of the abscess was lined with layers of fibrin. There were five ounces of bloody serum in the pericardium. The liver was filled with abscesses, from the size of a pea to that of a nut; some of them had only fibrin in them, others pus. In all reptiles there was a communication between the portal vein and the intercostals, and this was freer in the python than in other reptiles through an extra communication. The abscess was situated in the anastomotic area, and led to the hepatic abscesses and the pericarditis.—In reply to the President's question as to the cause of the abscess, Mr. SUTTON said that abscesses were common in snakes, possibly from wounds of the in-

testines produced by the bones which they swallowed.—Sir JOSEPH FAYRER, in reply to Dr. Wilks, said he was only familiar with multiple abscesses of the liver in the human subject, and he thought that at first they were limited necroses, and then abscesses.

Dr. WALTER EDMUNDS showed microscopical specimens of Nerves from three cases of Infantile Paralysis. The specimens were from three cases in which the leg had been amputated late in the disease as an encumbrance. The sections were from the internal popliteal nerve. They showed considerable increase of the endoneurium in the nerve-bundles and atrophy of many of the nerve fibres. The endothelium in the vessels in the nerve was proliferated.—Dr. BUZZARD thought that if the disease be really inflammatory it would probably affect the vessels in the connective tissue first, and where the inflammatory change was the greatest the nerve tubules would be most pressed upon, and therefore atrophied.—Mr. BOWLBY thought Dr. Edmunds' view was the correct one, as the separation of the fibres from the nutritive nerve cell would lead to atrophy. He thought the patches of connective tissue were in the site of former motor nerve fibres.

Dr. HALE WHITE and Dr. EDMUNDS showed microscopic specimens of Neuromata after Amputation, which were, he said, rare in the Society's Transactions, though not really rare tumours. The specimens showed that the first change in the coiled bundles of nerve fibres at the end of the amputated nerve was an ingrowth of delicate connective tissue from the perineurium; this ended in the sclerosis of the bundles, and in its turn the sclerosed tissue underwent fatty degeneration. The reason why the nerve fibres underwent fatty degeneration was that in man the other tissues of the limb not regenerating themselves, there was no need of either sensory or motor nerves. It was pointed out that in the nerve of the amputated limb certain fibres underwent degeneration, which were probably those coming from the parts which had been renewed, whilst the fibres which had not undergone degeneration were derived from the remaining parts of the limb. In a case of amputation of the thigh, the change in the cells of the tractus intermedio-lateralis had not extended as high as the lower dorsal cord. Sections of the median nerve just below a spot where it had been cut through previously showed complete degeneration of the nerve owing to all its fibres being functionally useless. A specimen was also shown of a round-celled sarcoma at the end of an amputated nerve.—Dr. WILKS asked if there was new growth as well as atrophy.—Dr. HOGGAN thought that the only satisfactory method was to begin *de novo* the study of nerve pathology by the investigation of the changes in the individual nerve fibres by the improved methods of staining by osmic acid and gold.—Dr. WHITE, in reply, said that his specimens were taken when the changes were too far advanced to show the new nerve fibres, and he had only quoted from the authorities as to their existence.

Dr. GOODHART showed the Calvaria and specimens of the other bones of an infant, aged fifteen months, who was in the hospital only three days, and died of atelectasis. The mother contracted gonorrhœa from her husband and the child had consequent ophthalmia, but there was no other evidence pointing to syphilis. There are two other children, one with rickets. The patient was suckled for three weeks, and then brought up on milk and water and beef-tea. The child thrived well the first year but always perspired profusely, had thrush badly, and occasionally spots on the nates, the abdomen was always large. During the last three months the spine had been curved and she cried when moved. A month ago the legs became swollen, then the arms, and then the head. There was well-marked cranio-tabes, the ribs were beaded and the thorax flattened laterally. Node-like lumps could be felt over the inner surface of each tibia and radius, and the lower epiphyses of the radii were enlarged. The spleen was notably enlarged. Post mortem the changes in the bones were the most noteworthy, the bones of the skull being enormously thickened, and also all the long bones and the spine. To summarise the changes:—1. The bones were soft like sponge, and all of them except the petrous part of the temporal bone could be cut with a knife like a raw potato, and one tibia was broken. 2. There was great hypertrophy, mainly, but not exclusively, upon the periosteal pattern. 3. There was marked rickets. The question was whether it was all from rickets or due to congenital syphilis. Parrot has described a similar condition of spongiform osteo-

phytes, but less marked than in this case, which he ascribes to congenital syphilis. Dr. Goodhart thought there was almost too much periosteal growth for rickets, and perhaps the safer plan was to consider it the outcome of both diseases. The infiltrating growth, which even obliterated the medullary canal, seemed to bring it in some relation to osteitis deformans, and some thought osteitis deformans was allied to tumours; and it might be suggested that these changes were more of the nature of a bone tumour.—Dr. NORMAN MOORE thought that the bodies of the vertebrae did not present the changes seen in rickets, and that in the skull the thickening was not increased at the sutures; in both these points it was not like rickets.—Mr. KESTEVEN asked if there had been any microscopical examinations made.—Dr. GOODHART replied that he had only made an imperfect microscopic examination, and found porous bone. He then related a case of Addison's Disease without bronzing, and showed the abdominal sympathetic nerves which had been carefully dissected out by Mr. Pearson, of the College of Surgeons. The patient was a medical man who had felt ill for a short time and took a sea voyage to recruit himself, obstinate sickness set in, which was ascribed to the effects of the sea, and he landed in a very exhausted state; a few days later he got out of bed and fatal syncope ensued. There was no alteration in the colour of the skin. At the autopsy Dr. Goodhart found suprarenal change, and the abdominal sympathetic affected in such a way as to show that there was undoubted Addison's disease. He thought that the case supported the view that if the disease was rapid in its course bronzing might not occur.

Mr. VICTOR HORSLEY exhibited specimens of Bone and Brain Disease in Syphilis. The organs shown possess no special interest beyond the fact that successful treatment lessens the opportunities of studying syphilitic lesions. In this case the patient was admitted into University College Hospital under Mr. Hill, from the Lock Hospital, Soho, in a very weak state, and suffering from pyæmic abscesses. What history could be obtained showed his condition to be pyæmic, following on necrosis of the facial and cranial bones. The specimens show, first, the points of necrosis on the frontal and malar bones, together with the spongy bones of the nose, of which the inferior turbinate was found post mortem to be a mere sequestrum, and kept in the nasal fossa by tenacious mucus. The whole mucous membrane of the pharynx is hyperæmic, and shows a few cicatrices of previous ulceration. The seats of active mischief were excessively foul, the smell of the discharge not being controlled by antiseptics. The frontal bone shows very well the cicatrices of former ulceration and destruction of the outer table. The lungs on both sides showed some cirrhosis of the apices and broncho-pneumonia; the liver, fatty and cirrhotic, presented a depressed scar on its surface penetrating a quarter of an inch into the substance of the organ. Both spleen and kidneys were cirrhotic, while the former was greatly enlarged, being seven inches long by four inches and a half by two inches. The other abdominal organs showed no particular lesion. On removing the brain there was found an excess of cerebro-spinal fluid, while the arachnoid and pia mater at the base were opaque, and in places matted together by exudation. This did not seem to have caused any paralysis of any cranial nerve. There is asymmetry of the cerebellum, the lateral lobe of the left side being deficient on its under surface at the anterior border, the flocculus being scarcely represented. This does not seem to be the result of disease. There were eleven abscesses in the connective tissue of the limbs and trunk.

Mr. HORSLEY also showed the Micro-organisms of Pyæmia. There were also shown two specimens of Micrococci, found in the abscess fluid of the case of syphilis and pyæmia first referred to, and also from a case of excision of the tongue for epithelioma. The form of pyæmia in both cases was alike—viz., that in which there is a formation of peripheral, not visceral abscesses—i.e., an infective process not dependent on embolism. As has always been found, the organisms are micrococci, and while always occurring in the abscess cavities, they were not found in the blood. With the fact in view of their invariable occurrence in acute abscess (described by Ogston and confirmed by Mr. Horsley), of course no causative importance was attached to their presence.

Card specimens of Urinary Calculi, chiefly composed of carbonate of lime, from the horse, ass, and dog, were shown by Mr. SHATTOCK; and Cancer of Omentum by Dr. BEDFORD FENWICK.

## OBSTETRICAL SOCIETY OF

A MEETING of this Society was held Dec. 6th, 1882, Dr. Matthews Duncan, chair.

*Deciduous Membrane.*—Dr. CLEVELAND finger-like sac, passed forty-eight hours patient who after a former labour had passed in stance, which he had then exhibited to careful search he had found no trace of. The PRESIDENT could think of no other unbroken decidua than that it came from.—Dr. WYNN WILLIAMS described a case present under his own care.

*Microscopic Sections of Carcinoma.* showed microscopic sections illustrating disease of the cervix complicating pregnancy of stroma was small compared with the appearance thus resembling that of med

*Perimetric Abscess.*—Mr. GRIFFITH showed a perimetric abscess, situated behind the ligament, displacing and obstructing the ing at three places into the cervix uteri.

*The Directions of Uterine Contractions.* showed a uterus removed by Porro's operation, illustrating well the wrinkles on its peritoneum the contraction of its muscular fibre. ROUTH had heard the uterine souffle present in cases in which he had failed in tating the abdomen.

*Retained Placenta.*—Dr. WYNN WILLIAMS showed a placenta retained for three months removed by him.

*Fibroids removed by Abdominal Section.* exhibited five specimens of uterine fibroids, respectively 3 lb., 8 lb., 13½ lb., 3 lb., and 1 lb., a abdominal section. One patient died each case the pedicle was secured by upon the value of which Dr. Bantock thought that whatever might be the future of cure of fibroids, it could not compete cases such as those exhibited, in each substantial objections to the former of BARNES thought fibroids such as Dr. D better dealt with by hysterectomy. to think Battey's operation best suited the wall of the uterus, and projecting and myxomatous tumours it was better could speak from clear observation of Battey's operation upon fibroids. this operation he had found a tumour practically gone.—Mr. KNOWSLEY thought hysterectomy should be performed if rectomy had been tried and failed. operation ten times; in all the patients been benefited, and in all the uterus in some to a surprising degree. N but the tubes, and the large vesment, ought to be removed.—Dr. Mr. Thornton's statement as to one by him.—Dr. CHAMPNEYS asked Mr he thought the operation should be thought only in cases in which life

*New Lamp.*—Dr. AVELING exhibited Swau's incandescient carbon lamp, introduced into cavities of the body for microscopic purposes.

*Ruptured Perineum: New Method.* paper upon this subject, by Dr. read. In this operation the sides denuded in the usual way; then about two-thirds of an inch in width, thickness, and long enough when high as the denuded surface on the from the floor of the vagina. S through the denuded surfaces in the edges as well as the flat surface with the raw surface. This being secured in the usual way. When sphincter ani, the flap was made through it in the same way as in the rent in the wall of the rectum was

ade to terminate within the bowel, and the deep sutures sutured before those bringing the flap into position were made.—Dr. AVELING asked what was Dr. Wynn Williams's attitude with regard to the action of the bowels after operation.—Dr. BANTOCK objected to the practice of tying the intestines together, and also to the use of vaginal injections, after operation. He had performed Dr. Wynn Williams's operation once, but was not much impressed by it.—Dr. LLEVELAND thought that rupture of the perineum could not be prevented by restraining the too rapid emergence of the child's head, which could be done by judicious counter-pressure.—Dr. SAVAGE thought the difference was overlooked between mere tegumentary lesions and rupture extending through the perineal body. In Dr. Williams's operation a narrow tongue of tegument was reserved in the course of denudation, and plastered over the crevice left after bringing the raw surfaces together. No additional strength resulted from this, because the tongue was merely tegumentary. Early operations were tegumentary, and failed together. The perineal body was the centre of attachment of the perineal muscles, and the mainstay of the floor of the pelvis.—Dr. ROUTH thought that rupture of the perineum could not always be prevented, and sometimes a slight laceration was not so great an evil as prolongation of the labour. He had in early practice succeeded completely with ordinary sewing-needles and thread. He concurred with Dr. Savage's remarks as to the perineal body, but had seen that the perineum made by Dr. Williams's operation was remarkably strong and effective.—Mr. KNOWSLEY THORNTON thought this mode of operating gave remarkably good results; but it was not new, having been described by Mr. Teale of Leeds, and practised by many American surgeons.—Dr. MURRAY had seen the operation now described, and thought it gave a firm perineum. It was not always prudent to retard the progress of the head. Laceration of the perineum might often be prevented by making one or two lateral cuts.—Dr. CAMPBELL POPE said that primary union might often be obtained by applying a broad strip of plaster to hold the edges together.—Dr. EDIS said that rupture might often be prevented by straightening the legs while the head was emerging, and also by making a nick on either side of the perineum. Union might be obtained by operation twelve or twenty-four hours afterwards. It was unnecessary, and rather jeopardised healing, to keep the bowels constipated after operation.—Dr. CULVER JAMES had, in one case, operated immediately after labour with a rather large common household needle, and obtained union.—The PRESIDENT had seen the results of many methods of operating, and could not say that one was better than another. He had stitched up a perineum two weeks after delivery without denudation or cutting of any kind, and it healed sufficiently.—Dr. WYNN WILLIAMS did not confine the bowels after operation. The perineum made without the flap he had described was apt to be too thin. He was not aware that his operation had been described before; it certainly was not alluded to in any work on gynecology.

*Pregnancy complicated with Cancer of the Cervix; Cesarean Section; Recovery.*—This paper, by Dr. EDIS, was then read. The patient came to the Middlesex Hospital in November, 1881. She had begun to suffer from pain, hæmorrhage, and discharge eleven months previously. She presented the signs of six months pregnancy, and there was epithelioma involving nearly the whole circumference of the cervix and the greater part of the posterior vaginal wall. Palliative treatment was adopted until February, 1882. Labour pains then came on, and the os dilated to the size of a five-shilling piece. It being judged impossible for delivery *per vias naturales* to take place, Cesarean section was performed by Mr. Morris. The child was born in a state of suspended animation, but recovered. The mother recovered, and when seen in September the disease had made but little progress.

*Two Cases of Labour complicated by Cancer of the Cervix Uteri.*—These cases were related in a paper by Dr. HERMAN. In the first case the diseased tissue was freely cut away with scissors and the actual cautery, and delivery effected with forceps. A vesico-vaginal fistula subsequently was formed, then phlebitis, and the patient died on the 18th day. The fistula occurred at a spot which the cancer had invaded. In the second case masses of diseased tissue were removed with the écraseur, the fingers, and scissors, with only trifling hæmorrhage, and delivery was effected with forceps. The mother recovered well. The author thought that in the management

of labour obstructed by cancer, the first alternative to be considered should be whether it was not possible to break down, and tear or cut away (the former preferably) the obstructing diseased masses.—Dr. BATE had had a case of labour with commencing cancer, in which delivery was effected by natural efforts, but the patient died from septicæmia.—Dr. CHAMPNEYS said that in these cases it was perhaps most important that there should be healthy tissue at the sides of the cervix, for it was there that lacerations most often occurred.—Dr. GALABIN inquired as to the method of suture of the uterus adopted in Dr. Edis's case. He had in four cases of cancer delivered *per vias naturales*, in one only was there great difficulty in doing so; but two of the mothers died; in one of the latter the disease was almost entirely removed with the galvanic cautery.—Mr. JENNINGS thought that rupture of the bladder during parturition was not so rare as might be supposed.—Dr. FANCOURT BARNES thought that in these cases Cesarean section offered a chance of probable recovery to the mother and certain safety to the child. An important point was that in this operation healthy tissues were cut through, while in natural delivery diseased tissues were torn, thus favouring blood-poisoning.—Dr. EDIS said that in his case interrupted sutures of silkworm gut were used.

## ACADEMY OF MEDICINE IN IRELAND.

### MEDICAL SECTION.

The first meeting of the Medical Section was held in the College of Physicians on Friday evening, the 15th inst. Dr. William Moore, President of the King and Queen's College of Physicians, Ireland, occupied the chair as President of the Section.

The PRESIDENT delivered an inaugural address. Having alluded to the absorption of the Medical Society of the King and Queen's College of Physicians into the Academy of Medicine in Ireland as its Medical Section, he reviewed at considerable length the advances made in the diagnosis of disease, particularly within the last twenty-five years. He referred first to affections of the chest, the differential diagnosis of which was now well-nigh perfect. In certain cases clinical observations of the temperature had proved of great use, and the most recent advance was the demonstration by Professor Robertson of the germ origin of pulmonary tuberculosis. To Laennec was due the elucidation of cardiac diseases, and to Traube, in great measure, the knowledge of the relations which may exist between these and renal affections. The diagnosis of valvular diseases had become very exact, but the precise value of murmurs as regards diagnosis and prognosis was apt to be over-estimated. Nor was the diagnosis of abdominal aneurism always an easy matter. Great advances had also been made in the study of specific fevers, especially of the endemic fever of this country, enteric or typhoid fever. Again, much had been done in the localisation of cerebral and spinal diseases, among the more interesting of this class of maladies being hysteria, hystero-epilepsy, and hemianæsthesia. As regards the treatment of some of these affections, he mentioned some remarkable instances in which good results had followed the practice of metallo-therapy.

Mr. ARTHUR BENSON exhibited a case of well-marked Retinitis Albuminuria in a boy, aged sixteen, without constitutional disturbance; Dr. CHARLES F. MOORE, a case presenting Neuralgic Symptoms in a man having remarkable patches of white hair, some of which were congenital; and Mr. STORY a case of Double Zonular Cataract.

Dr. J. W. MOORE exhibited by card specimens of Diphtheritic inflammation of the throat; and Mr. P. S. ABRAHAM microscopic sections showing (1) diphtheritic deposit of muscular tissue of the pharynx; (2) mycelium of fungus; and (3) degeneration of muscular fibre in diphtheria.

Dr. WALLACE BEATTY read a paper on the Causation of Left-side Pain, drawing special attention to a form not sufficiently recognised, which was due to fecal accumulation, and removed by getting rid of the accumulation. The pain was felt over the lower few ribs on the left side, was associated with extreme tenderness on pressure upwards of the tenth or eleventh rib, scarcely any pain being felt on pressure of these ribs downward, and was relieved when the side was pressed inwards with the flat of the hand. He explained its occurrence by the drag of a loaded colon on the pleuro-colic ligament; this constant drag setting up a state of

extreme irritability in the nerves of that ligament, so that a painful impression was carried upwards along the left lesser splanchnic nerve to the spinal cord, and was transferred by the law of irradiation of sensations to the tenth and eleventh left intercostal nerves.—Dr. WALTER SMITH said the pleuro-colic fold had not received the attention it deserved. It certainly was of considerable importance in the investigation of abdominal disease. Dr. Beatty's arguments were valid as explaining certain kinds of left-side pain, but did not explain all kinds.—Dr. WALLACE BEATTY did not wish it to be understood that he considered left-side pain was caused in every instance by faecal accumulation, but only in cases presenting the symptoms he had mentioned.

Dr. WALTER SMITH related two cases of Paralysis of the left half of the Velum Palati, and raised the question whether palatine paralysis was invariably to be regarded as a characteristic sequela of diphtheria, or whether it may not occasionally supervene upon non-diphtheritic forms of angina. Case 1 occurred in a young lady, aged twenty-four, and the paralysis developed six weeks after an apparently simple ulcerated sore throat, for which she had been treated by Dr. Smith. Case 2, a young lady, aged twenty-six, was affected with what was considered to be a simple relaxed sore throat unattended with ulceration. She remained in a weak and nervous condition, and shortly afterwards the left half of the palate was found to be paralysed. In each case the symptoms were similar—viz., difficulty of swallowing, nasal twang in the voice, and regurgitation of fluids through the nose. Both cases recovered completely. Dr. Smith submitted that it was not unreasonable to hold that catarrhal sore-throat may now and then give rise to slight motor paralysis through partial implication of the nervous system or otherwise.—Dr. HENRY KENNEDY said that diphtheria might exist without exudation. He had seen such cases in which paralysis followed.—Mr. H. G. CROLY said that the large majority of cases described as diphtheria were really cynanche.—Mr. WILLIAM THOMSON asked, if paralysis occurred in the palate as the result of specific inflammation, why similar effects did not follow in other parts of the body where nerve filaments were concerned.—Mr. J. W. MOORE alluded to the specimen which he exhibited, describing it as one of phlegmonous erysipelas of the throat in which diphtheritic conditions had supervened. He believed that paralytic symptoms occurred only in true diphtheria.—Dr. FINNEY considered the fact that other diseases were associated with paralytic symptoms confirmed Dr. Smith's view.—Mr. W. STOKES doubted that paralytic symptoms followed inflammation other than those of a diphtheritic nature.—The PRESIDENT regretted that no information had been given as to the presence of albumen in the urine in Dr. Smith's cases.—Dr. R. A. HAYES mentioned in support of Dr. Smith's view a case in which chronic inflammation of the palate, resulting from excessive tobacco smoking, gave rise to paralysis of the palate.—Dr. WALTER SMITH, in reply, said that the paralysis in these cases might be the result of myelitis or of muscular degeneration. He answered Mr. Thomson's question by pointing out the rich nervous supply of the palate, and the muscles being open to attack from both sides.

The Section then adjourned.

## Reviews and Notices of Books.

*Etudes de Physiologie Sociale: La Prostitution.* Par YVES GUYOT. Paris: G. Charpentier. 1892.—This laborious work has been written with the well-conceived purpose of proving that the various legislative measures in force with regard to prostitution, in their relations to the preservation of the public health and morals, have not only altogether failed in these respects, but have exaggerated the evils they were intended to suppress. We will see upon what grounds, and by what arguments, the author supports these positions, and to what extent he has succeeded in establishing them. He commences by asking, "What is prostitution?" and, accepting the definition of Littré—"An abandonment to unchastity"—very properly remarks that the term is applicable to either sex. But when he pushes his premises farther, and claims for the word "prostitute" a similar lati-

tude, he contends for a point of no practical importance as it is universally understood to mean woman. He then gives a graphic account of the atrocities exercised against this unfortunate at various times and in divers countries, Solon and Charlemagne to more recent periods, and is eloquent on the effects of the unequal laws and relations between the sexes; but though full of pity that the insanitation and infamy of prostitution should be punished and not of the other, yet he has no remedy for them. It appears, from his remarks on the subject, that until the nineteenth century regulations with regard to prostitution were not till the period mentioned that the question was conjoined with it. With a minute and revolting in its gross indecency, and the author would have dared to have published the *modus operandi* of the "French system" by "the police of morals," together with the connected therewith. The primary object would seem, is to concentrate prostitution in licensed houses, "*des maisons de tolérance*" as far as possible, to certain districts; to attain this the author says that its admission is "brutally harsh, venal, and unjust." a moral degradation of both the women and so frightful a nature that it is appalling and we may well felicitate ourselves that it encourages or permits the herding together of women in one house, under the tutelage of "*la maîtresse de la maison*," who, through her abominable traffic, has not any legalised existence in this country, an assertion to the contrary. He says of the Contagious Diseases Act license increased at Aldershot, and the police movement." We are in a position, if instituted on these points, to give an answer. The authorities say "such a system is decreased, as has also the number of young girls are now seldom seen in the streets, can be more explicit than this, an advertisement; for it would be impossible to mean of undermining the health of the rising generation than by legally prostitution such as has been so realistic author. It is, however, in its relation to the fact that this system more immediately concerns its own Contagious Diseases Act, its purpose, is largely modelled on that which applies to sanitation. Here the author failed to make out his case. How can he establish it? In the first place, being relatively more venereal disease in licensed houses, who are medically supervised than amongst *les filles isolées*, furnished rooms, who are obliged, to the dispensary once a fortnight for medical intervention in this respect amongst them. He himself has no proof of the fallacy of this doctrine, "that while the former cannot exercise selection of their clients and are of a greater number, six to twenty-five, exercise that selection and are able to the number of their reception, "the first are always amenable to the others are made to submit with them often go away when diseased hospital." Comment on this is a

called in this way are worse than useless. Another argument he advances in support of this position is that "it is almost impossible to discover a primary infecting chancre or decide the nature of vaginal discharges in a woman." This assertion is contrary to experience, for though, no doubt, it may be difficult in some instances to detect the difference or differentiate between the several kinds of the other, in the majority of cases it will not be so. Besides, irrespective of this, are not syphilitic mucous patches infective? And is there anyone so obtuse as to deny that when the object of them is sent to hospital for treatment a fruitful source of infection has been withdrawn from circulation? It is idle to attempt to refute such statements as these, and those who are agitating for the repeal of the Acts in question have no stronger testimony to bring forward than this their case is desperate indeed. The French term is utterly demoralising, but the legislation exercised in this country has an opposite effect, for it has been proved by numerous letters in THE LANCET and elsewhere, and by other testimony, that many young women, more impressionable than those more hardened in sin, have been rescued from their evil courses by the interposition of these Acts, and this is a sufficient answer to a favourite theory of the reformers that "the duration of time during which prostitutes exercise their calling has been greatly prolonged by the influences they have exerted." If they are enforced efficiently, and the medical examinations are conducted with proper skill and care, it is absurd to suppose that the diseases for the prevention of which they were passed are not correspondingly ameliorated. M. Guyot's elaborate ventilation of this subject will undoubtedly do good, and we strongly recommend all interested in it to read the book for themselves.

*Metropolitan Sewage, and what to do with it.* By EDWARD MONSON, A.M.I.C.E. Part I. London: Prentice and Sonson.—Mr. Monson's small work appears opportunely at a period when so much attention, both public and private, being given to the condition of the Thames as the result of the metropolitan outfalls for sewage. The whole history of the London sewerage system, and of the formation of the Metropolitan Board of Works, is entered into, and much of the action of the board is sharply criticised, both on account of the plan on which some part of the sewerage works have been designed, and because the scheme has never been carried out in its entirety. Especially does the author complain that flooding of houses, insufficiency of sewer provision, needless expense, and other difficulties have resulted from the initial error of not separating streams with much of the rainfall and the storm-water from the sewage proper. The sewers are in consequence of enormous size; they are, notwithstanding their huge capacity, totally inadequate to carry off storm-water, and the sewage which, under a separate system, could have been concentrated at a point where it might easily have been either chemically treated or utilised, is so diluted and in such quantity that the question of its proper disposal has never been faced. As a result, the effect of discharging the metropolitan sewage into the Thames has been to cause a nuisance of imperial magnitude and concern; shoals of sewage mud are found in the river; and very general complaint emanates from the Thames Conservancy, the Port Authority, and the riverside population. Even now Mr. Monson maintains that there would be true economy in reconsidering the system as a whole, and he specially advocates that the sewage should be treated by the lime process before the effluent is passed into the river. With regard to the sewage sludge which would result from this process, Mr. Monson points out how much it partakes of the character of the washed clay and chalk used in the manufacture of stock bricks; and he shows, as the result of actual experiment, not only that in this direction will in all probability be found the remedy for that accumulation of

apparently useless sludge which has so often been associated with the lime process of dealing with sewage, but that the utilisation of the sewage sludge in the manner he proposes will open out a great future for the manufacture of a brick which will be much sought after in building operations.

*On Duty under a Tropical Sun:* being some Practical Suggestions for the Maintenance of Health and Bodily Comfort, and the Treatment of Simple Diseases, with remarks on Clothing and Equipment for the Guidance of Travellers in Tropical Countries. By Major S. LEIGH HUNT and A. S. KENNY, M.R.C.S.E. pp. 138. London: Allen and Co. 1882.—The object of this work is to assist persons visiting tropical climates to counteract and palliate many of the petty annoyances and personal discomforts to which, from lack of experience, they may be exposed. The remarks on diet and the suggestions on clothing and equipment seem well calculated to be useful to the class for whom they are intended, but we are afraid that the remarks upon the diseases of tropical climates and the directions for their treatment will rather have a tendency "to foster a false sense of security by leading anyone to think it is possible for him to dispense with proper medical assistance when these evils befall him." This is far from the intention of the authors, who endeavour to impress upon their readers the "imperative duty" of availing themselves of the skill and experience of medical men acquainted with the diseases of the country; but we entertain doubts as to the practical results of the attempt in the direction of "domestic medicine."

*What to do in Accidents and Sudden Illness, &c.* By PHILIP FOSTER, M.D. Pp. 76. Leeds: Spark.—This is one of a class of books which, if not called into existence, has, at least, been greatly developed by the formation of ambulance classes. The work now before us is not, however, confined to instruction in what should be done on the occurrence of an accident or the infliction of an injury, but covers a much more extensive field. It discusses the conditions necessary for the preservation of health and the prevention of disease among the people generally; the duty of sick nursing; "the symptoms and treatment of certain ailments for which medical advice is frequently not sought, and of some others in which serious consequences might ensue before it could be obtained," including cases of poisoning; and concludes with a few remarks on the rearing of children. The work seems to have been carefully drawn up, and on the whole to be judicious and well calculated to answer the purpose intended. We think, however, it might have been abridged without detriment by the omission of the introductory chapter on the structure and functions of the body; and we must protest against the author's opinion that "the duties pertaining to the office of the nurse do not call for special knowledge or training." There may possibly be good nursing without these, but it is the rare exception to the rule. We hold that no greater improvement has taken place in the treatment of the sick than the introduction of a thorough practical training of the nurse.

*Diseases of the Ear.* By GEORGE P. FIELD, M.R.C.S., Aural Surgeon to St. Mary's Hospital, and Lecturer on Aural Surgery in the Medical School. Illustrated with coloured plates and woodcuts. London: Henry Kenschaw. 1882.—We have noticed the previous editions of this book, and are not now surprised to receive a third edition. The class of diseases of which it treats are of great importance, and yet unfortunately are seldom the subject of much attention in medical education, either on the part of the student or his teachers. Mr. Field does his best, and does well, to make up for this defect. His book will be found very useful both by students and practitioners. This

edition contains many new illustrations and several additional chapters.

*Monthly Maxims.* By ROBERT DUDLEY. De la Rue, 1882.—The close of the year brings with it the annual cluster of books suitable for presents, and the volume before us is one which will do much to enhance the reputation of both artist and publisher. Mr. Dudley's illustrations afford a rare combination of daintiness, delicacy, and quaint humour, and show in the drawing and execution a carefulness which is very seldom seen in works of this class. The larger illustrations are magnificent specimens of chromo-lithography, and this book of *Monthly Maxims* is one of those "things of beauty" which we feel sure will live far longer than the conventional ephemerides in company with which it makes its appearance.

*Introduction to Latin Prose Composition, with Hints on Latin Writing and Periodic Style.* By R. M. MILLINGTON, M.A. London: Longmans, Green, Reader, and Dyer, 1882.—Although the study of the Classics is now considered of much less importance than heretofore, almost all allow that the study of Latin composition may be a valuable mental training. Mr. Millington's book contains a carefully graduated course of Latin prose composition—a course which, if conscientiously gone through, is quite sufficient to satisfy the most rigorous examiner. The notes to each exercise are especially valuable, and the hints on style &c., and the repeated warnings against the indirectness of expression and want of harmony which characterise the compositions of many candidates at our university examinations, should be borne in mind by the student. Cicero, Livy, and Cæsar are, according to custom, recommended as models; and the by this time familiar warning against the terseness of Tacitus is given—a warning in which we, who have often enjoyed the "word-pictures" of that master of brevity, cannot join. A book of similar character on Latin verse composition would be valuable, and we hope that, should the present volume meet with the success it deserves, Mr. Millington may turn his attention to such a work.

*Sixes and Sevens.* Written by F. E. WEATHERLY; illustrated by JANE M. DEALY. London: Hildesheimer and Faulkner. Amongst the eligible presents for young folks at this season "*Sixes and Sevens*" must occupy a very high place. It is difficult to decide as to the comparative merits of verse and illustrations, both are so excellent and so well calculated to effect the object aimed at—the amusement and instruction of juvenile readers. The book will assuredly become a favourite in the nursery.

## New Inventions.

### A PORTABLE STETHOSCOPE.

THIS is an ingenious and elegant instrument, the stem of which is composed of a jointed tube of aluminium, so that it can be drawn out to the extent of six inches, its length when closed being less than three inches. The chest and ear pieces are made of celluloid, and the latter can be removed from the stem, to which it is fitted by a screw. By these devices the instrument becomes the most portable of any stethoscope with which we are acquainted. It remains to be seen how it will stand the wear and tear of daily use; but that it is quite as efficient a conductor of sound as the ordinary wooden stethoscope we have assured ourselves by considerable trial. The stethoscope is made by Messrs. Salt and Son, of Birmingham.

THE members of the St. John's Institute at Burgess-hill, Sussex, have decided to raise a memorial to the late Dr. James Braid.

### HIS EXCELLENCY THE GOVERNOR-GENERAL OF CANADA AND H.R.H. PRINCESS LOUISE IN VANCOUVER'S ISLAND.

R. W. BURNET, M.D., M.R.C.P. (Physician to the Northern Hospital), has favoured us with the following descriptive sketch:—

In the Province of British Columbia, lying between forty-ninth and sixtieth degrees of north latitude, and extending from the Rocky Mountains on the east to the Pacific Ocean on the west—an area about three times as large as that of Great Britain and Ireland,—there must of necessity be considerable differences of temperature and variety of climate. The prolonged stay of the Marquis of Lorne and Her Royal Highness in Vancouver's Island of itself is well for the climate of Victoria and the healthiness of the country. The mean winter temperature is set down at 45°, and that of summer rather more than 60° F., which is considerably higher than the average on the mainland. The mildness of the climate for over three hundred miles west of Victoria is attributed to the warm Japanese current which is believed to strike the Queen Charlotte Islands and flow in a southerly direction along the shores of Vancouver's Island. The rainfall of the islands and coast of the mainland varies, in different places, from forty-five to eighty inches. In some parts of the interior the rainfall is abundant, and in others, owing apparently to the position and relations of the mountain ranges, the fall is much less, and in dry seasons irrigation has to be taken advantage of to secure good crops. In consequence, however, of the large number of streams, a good water-supply is easily obtained. The mountain districts extending into high latitudes have greater variations of temperature—a long day in summer and a winter resembling that of Manitoba and the other northern territories.

As Los Angeles, Santa Barbara, and other favoured regions of Southern California form a sanatorium for the more temperate regions of the States, so there seems every probability that Victoria, and the whole southern part of Vancouver's Island, will, when the direct railway is opened, become a resort for those dwellers in the great Canadian North-West who have to seek milder air, or who desire to escape the rigours of a winter such as is usual in those parts. The direct communication between British Columbia and the other provinces of Canada has to be by way of San Francisco, and when the Canadian Pacific Railway, now in process of construction, is opened, the connexion between the provinces will be direct and complete, through scenery destined to attract those who have seen both to be equal in places to be seen in the Alps. The railway will then be connected with the English steamers arriving at Halifax, and the shortest route from England to China and Japan. There is still a considerable Indian population on these islands, but they are very much inferior in appearance and physique to those of the plains on the east of the Rocky Mountains. They are quiet, law-abiding, and industrious, engaged in agricultural and other pursuits. On the Fraser and other rivers, where salmon fisheries form a very important part, the fishing is entirely done by Indians. Whisky and rum have, however, made great ravages amongst them, and are steadily decreasing in numbers.

The inhabitants of Victoria, numbering about 6000, English and Scotch, are comfortable, easy-going people. The necessaries of life are moderately cheap, and wages are high—any skilled workman making from four to six shillings a day. In such a community there is, as might be expected, not much need for large hospital accommodation. The Victoria Hospital has some thirty beds and stands on a dry, elevated site, a short way out of the town. Esquimaux, some four or five miles off, there is a small hospital near the dockyard, and to it a resident surgeon is attached. Besides these there are the small Free Roman Catholic hospitals, and the small district hospitals of New Westminster and Navarino. At the last named place there are extensive and increasing coal workings, in which a large number of men are employed.

Her Royal Highness the Princess Louise lately paid a visit to the Royal Victoria Hospital, and was received over it by Mr. J. B. Matthews, M.R.C.S. Eng., a student of St. George's Hospital.

# THE LANCET.

LONDON: SATURDAY, DECEMBER 30, 1882.

## THE ANNUS MEDICUS 1882.

### Introduction.

WE proceed to lay before our readers a history of the year 1882, not pretending that it is complete. As on previous occasions, we go at once to our duty without preface or comment on the general history of a year which, with all its faults, will not look badly in British history.

### Anatomy and Physiology.

Before referring to a few of the more noteworthy of the facts which have advanced our knowledge of Anatomy and Physiology during the past year, it is with feelings of no ordinary emotion that we notice the death of CHARLES DARWIN, the great naturalist, whose work, continued through a long period of bodily infirmity, has left a durable impress on the whole world of modern thought; who passed away in the spring at the ripe age of seventy-one, and who lived long enough to see that the calm and unimpassioned, yet logical mode in which he stated his opinions, and the vast array of facts resting on unimpeachable authority he brought to support them, had converted to his doctrine many of those who by education and vocation were most disposed to ignore, scoff at, and oppose them. In the next place, it is fitting to express our deep feeling of regret at the loss science has experienced at the death of Professor FRANCIS M. BALFOUR, of Cambridge, a brilliant follower of DARWIN, and to pay a tribute of respect to the excellence of the work on Comparative Embryology, which he had only just completed, and which promises to be for a long time the text-book on this subject. The observations he had made are to a very large extent original, and though time has not yet been afforded to enable them to be corroborated by other observers, yet the care with which they were undertaken, the rare manipulative dexterity he possessed, and the acuteness of his perceptions, combined with the habitual caution with which he formed his opinions, render it probable that they will meet with very general acceptance. The statements made are everywhere well arranged and easily accessible to the student. The next works to be mentioned are the several splendid volumes of the reports of the scientific results of the *Challenger* expedition, to which we have on various occasions directed the attention of our readers, as containing an immense amount of original information upon the inhabitants of the deep sea, and many beautifully executed drawings of animals new to science, with descriptions by such men as MOSELY, HAECKEL, and others thoroughly versed in the anatomy and physiology of the animals of which they treat. There have not been many additions to the existing and well-known treatises on anatomy and physiology during the past year, though several new editions have appeared. Thus of the former we have only to enumerate Mr. REEVES' *Morphology*, a work of considerable originality and research. Dr. MEARS has written a work on *Schematic Anatomy*, which is on a new principle, and presents some advantages to the learner.

The first part of a good system of Comparative Anatomy has been published by WIEDERSHEIM, and the first fasciculi of Treatises on Zoology, by LANESSAN and by MOQUIN TANDON, have been issued, the last, however, being a translation of a new edition of CLAUS, a work already well known. Amongst the new editions may be mentioned QUAIN'S *Anatomy*, which has been considerably enlarged, and in which the Histology has been carefully revised by Mr. SCHAEFER, the Embryology and Development by Dr. ALLEN THOMSON, and the Anatomy by Professor THANE, assisted by Mr. GODLEE, rendering it upon the whole the most complete work of the kind in any language. A third edition of Professor MAPOTHER'S work on Physiology, revised by Dr. KNOTT, has appeared, and Dr. DALTON has issued the seventh edition of his excellent Physiology, which has the rare merit in physiological works of being somewhat less voluminous than its predecessors without losing in clearness and precision. A second edition has also appeared of HARRIS and POWER'S *Manual for the Physiological Laboratory*. Many important papers have appeared in the successive numbers of the *Quarterly Journal of Microscopical Science*, amongst which may be mentioned PRINGSHEIM'S and LANKESTER'S Researches on Chlorophyll, KLEIN'S article on the Lymphatic System, WALPOLE and HUXLEY on Saprolegnia in relation to the Salmon Disease, and HERBERT CARPENTER'S notes on Echinoderm Morphology. In the *Journal of Anatomy and Physiology* the segmental value of the cranial nerves has been discussed by Dr. MILNES MARSHALL. The cerebral sinuses and their variations have been described by Mr. J. F. KNOTT, and the volume issued during the present year contains many valuable articles on comparative anatomy. The *Journal of Physiology* contains papers by NEWELL, MARTIN, and SEDGWICK on the mean pressure and the characters of the pulse wave in the coronary arteries of the heart settling the question in favour of those who believe that the coronary arteries are injected during each systole of the heart and not during the diastole, and also an excellent paper by C. S. ROY, showing that the spleen performs rhythmical contractions independently of cardiac and respiratory movements.

In the "Leçons sur les Modifications du Sang," in which the changes presented by the blood under the influence of various remedies and therapeutic agents has been carefully investigated, GEORGES HAYEM has made a substantial addition to our knowledge of this fluid. By giving a table of the number of blood-corpuscles in a cubic millimetre, corresponding to every number from 40 to 270 of blood corpuscles counted in a square of a hæmatocytometer, he has materially facilitated all calculations of the absolute number of the blood-corpuscles. MALASSEZ has specially discussed the development of the red corpuscles in the medulla of the bones, and MAYET the spontaneous changes undergone by the coloured corpuscles preserved in plasma without access of air; whilst ALEXANDRE SCHMIDT has contributed to BROWN-SÉQUARD'S *Archives* a résumé of the researches made under his direction at Dorpat upon the physiological and pathological action of the leucocytes of the blood, in which he still continues to maintain that the white corpuscles contain a ferment that plays an important part in the act of coagulation, and having separated this ferment he shows its effects when injected into the economy. CADET, BIZZOZERO, HART, and others have

edition contains many new illustrations and several additional chapters.

*Monthly Maxims.* By ROBERT DUDLEY. De la Rue. 1882.—The close of the year brings with it the annual cluster of books suitable for presents, and the volume before us is one which will do much to enhance the reputation of both artist and publisher. Mr. Dudley's illustrations afford a rare combination of daintiness, delicacy, and quaint humour, and show in the drawing and execution a carefulness which is very seldom seen in works of this class. The larger illustrations are magnificent specimens of chromo-lithography, and this book of *Monthly Maxims* is one of those "things of beauty" which we feel sure will live far longer than the conventional ephemeridæ in company with which it makes its appearance.

*Introduction to Latin Prose Composition, with Hints on Latin Writing and Periodic Style.* By R. M. MILLINGTON, M.A. London: Longmans, Green, Reader, and Dyer. 1882.—Although the study of the Classics is now considered of much less importance than heretofore, almost all allow that the study of Latin composition may be a valuable mental training. Mr. Millington's book contains a carefully graduated course of Latin prose composition—a course which, if conscientiously gone through, is quite sufficient to satisfy the most rigorous examiner. The notes to each exercise are especially valuable, and the hints on style &c., and the repeated warnings against the indirectness of expression and want of harmony which characterise the compositions of many candidates at our university examinations, should be borne in mind by the student. Cicero, Livy, and Cæsar are, according to custom, recommended as models; and the by this time familiar warning against the terseness of Tacitus is given—a warning in which we, who have often enjoyed the "word-pictures" of that master of brevity, cannot join. A book of similar character on Latin verse composition would be valuable, and we hope that, should the present volume meet with the success it deserves, Mr. Millington may turn his attention to such a work.

*Sixes and Sevens.* Written by F. E. WEATHERLY; illustrated by JANE M. DEALY. London: Hildesheimer and Faulkner. Amongst the eligible presents for young folks at this season "*Sixes and Sevens*" must occupy a very high place. It is difficult to decide as to the comparative merits of verse and illustrations, both are so excellent and so well calculated to effect the object aimed at—the amusement and instruction of juvenile readers. The book will assuredly become a favourite in the nursery.

## HIS EXCELLENCY THE GOVERNOR OF CANADA AND H.R.H. PRINCE IN VANCOUVER'S ISLAND

R. W. BURNET, M.D., M.R.C.P. (Physician Northern Hospital), has favoured us with descriptive sketch:—

In the Province of British Columbia, lying forty-ninth and sixtieth degrees of north latitude, extending from the Rocky Mountains on the east to the Pacific Ocean on the west—an area about the same as that of Great Britain and Ireland,—there are considerable differences of temperature and climate. The prolonged stay of the Marquess of Victoria and the Prince of Wales in Vancouver's Island well for the climate of Victoria and the surrounding country. The mean winter temperature is 50° F. and that of summer rather more than 60° F. considerably higher than the average on the mainland. The mildness of the climate for over three hundred miles of the coast is attributed to the warm Japanese current which is believed to strike the Queen Charlotte Islands in a southerly direction along the shores of the island. The rainfall of the islands and coastland varies, in different places, from forty-five to one hundred inches. In some parts of the interior the rainfall is much less, owing apparently to the position and range of the mountain ranges, the fall is much less, and irrigation has to be taken advantage of to secure a good water-supply is easily obtained. In consequence, however, of the large number of districts extending into high latitudes have a low temperature—a long day in summer and resembling that of Manitoba and the other territories.

As Los Angeles, Santa Barbara, and other regions of the States, so there seems every prospect of the same in Victoria, and the whole southern part of Vancouver's Island, when the direct railway is opened, because of those dwellers in the great Canadian Northwest who have to seek milder air, or who desire to escape a winter such as is usual in those parts. The communication between British Columbia and the provinces of Canada has to be by way of San Francisco when the Canadian Pacific Railway, now in progress of construction, is opened, the connexion between them will be direct and complete, through scenery such as those who have seen both to be equal in places in the Alps. The railway will then be connected with English steamers arriving at Halifax, and this is the shortest route from England to China and Japan. There is still a considerable Indian population on these islands, they are very much inferior in appearance and those of the plains on the east of the Rocky Mountains. They are quiet, law-abiding, and industrious, agricultural and other pursuits. On the Fraser River, where salmon fisheries form a very important part of the fishing is entirely done by Indians. Whisky has, however, made great ravages amongst them and they are steadily decreasing in numbers.

The inhabitants of Victoria, numbering about 10,000, English and Scotch, are comfortable, easy-going. The necessaries of life are moderately cheap, and high—any skilled workman making from four to five shillings a day. In such a community there is, as might be expected, not much need for large hospital accommodation. The Victoria Hospital has some thirty beds and stands on a dry, elevated site, a short way out of the city. At Esquimaux, some four or five miles off, there is a small hospital near the dockyard, and to it a resident physician is attached. Besides these there are the small Roman Catholic hospitals, and the small district hospital at New Westminster and Navarino. At the last named place there are extensive and increasing coal workings, and a large number of men are employed.

Her Royal Highness the Princess Louise has paid a visit to the Royal Victoria Hospital, and was accompanied over it by Mr. J. B. Matthews, M.R.C.S. Eng., a student of St. George's Hospital.

nal exception, of small importance. The year has been specially barren so far as English pathology is concerned. From the laboratories of neither England nor Scotland has any important work proceeded, and even from the Brown Institution, from which we have had such good work in the past, comes the sound of physiology rather than of pathology. The lectures on Inflammation by Dr. BURDON SANDERSON, and on Pulmonary Activities by Dr. EWART, deserve, however, especial mention, though, in the former, we are not carried far beyond our obvious standpoint. Abroad, bacteria still absorb the energies of the pathologists of Germany and France, and the importance of the study has been sufficiently attested by the brilliant investigations which have added a new "household word" to the literature of pathology. Few recent discoveries have created a wider and more profound sensation than that of the tubercle bacillus, for which KOCH certainly deserves the high credit he has received, although the discovery had been worked towards by many investigators, and was made independently by BAUMGARTEN. The organisms of tubercle have given pathologists in all countries abundant work, and we may expect soon to have some definite facts bearing on its practical value, in addition to the technical facts regarding methods of observation which have been abundantly supplied. In other departments of bacterial pathology some new facts have been supplied, fewer in number, however, than in preceding years. Among them may be mentioned specially the researches of BIRCH-HIRSCHFELD on the organisms associated with syphilis, and of KEATING on those of measles, although the latter are scarcely more than a corroboration of the half-forgotten observations of VACHER and BRAIDWOOD. Of especial significance also is the fact announced by FEHLEISON, that the organisms of erysipelas are capable of giving rise to the disease after their separate cultivation. The remarkable observations of LAVERAN on the organisms which apparently constitute the active agent in the production of malarial disease, have been this year confirmed by RICHARD, and may perhaps excite more attention than they have hitherto received. Regarding other specific diseases the chief researches to note are those of POPOFF on the changes in the brain in typhoid fever, and those of EISENBERG on the alterations which are produced in the salivary glands by rabies. In the region of general pathology, the subject of inflammation has been little studied. Besides the lectures of BURDON SANDERSON, already alluded to, the most important researches are those of SPINA, on the morphological changes presented by protoplasmic elements in the tissues, which have not the form of cells. ZUNTZ has investigated the cause of the increased oxidation which occurs in pyrexia, and believes that the facts he has ascertained regarding the action of curara must, to some extent, alter our views of the process. The subject of septicæmia has been somewhat neglected during the past year, and the work which has been done only serves to show how much more is needed. The experiments of ROSENBERGER, for instance, suggest that the relation of bacteria to this condition may be secondary and not primary, and are of special interest in connexion with the facts which ROSSBACH has published, which apparently prove that, under certain circumstances, the organisms always present in the body may be the source

of those associated with septicæmia. The general pathology of the blood has attracted little attention, nor can we expect new facts until there is more agreement regarding its constituents. We must not, however, omit to mention the researches of HAYEM on the processes by which hæmorrhage is arrested, and on the peculiar "hæmatic crises" which occur during the course of many acute diseases. Apart from the question of its relation to bacteria, the pathology of tubercle has been the subject of many researches, and among those which deserve mention are that of CHIARI on the hyaline metamorphosis which tubercle undergoes; the laborious investigations of ARNOLD on the minute structure of tubercle in various organs; the studies of its formation in the thoracic duct by STILLING, and in the veins by WEIGERT, and in the synovial sheaths of tendons by TERRIER and VERCHÈRE. The facts described by TAPPEINER regarding the production of phthisis in dogs by the inhalation of tuberculous sputum have been confirmed by WEICHSELBAUM, although no new evidence of the contagiousness of phthisis in the human subject has been adduced. The observation of FRIEDLANDER may be regarded as demonstrating the frequent occurrence of organisms in connexion with croupous pneumonia, although it still leaves undetermined their precise relation to the disease. The etiology of gastric ulcer has been studied experimentally by AUFRECHT; the cause of the jaundice of newly born children has been investigated in a most able and thorough manner by BIRCH-HIRSCHFELD. No observations on the gastro-intestinal tract are more important than those of NOTHNAGEL on intestinal catarrh and atrophy, which, although undertaken from a clinical standpoint, are of great pathological interest. The occurrence of compensatory hypertrophy of the kidneys has been demonstrated by RIBBERT; and the researches of AUFRECHT have thrown considerable light on the pathogenesis of renal cirrhosis. Lastly, in what may be termed toxicological pathology, the most important investigations have been those of CORNIL and BRANLT on the effects of arsenic and phosphorus, which have shown the identity of the changes produced by the two agents.

#### *Therapeutics.*

In the department of therapeutics there are many indications of vitality and of distinct reaction from that scepticism as to the use of medicine which followed, as effect follows cause, the rise and fall of homœopathy. The demonstration afforded by this exploded system, in its simplicity, of the strong recuperative powers of the system, naturally led physicians to question whether medicine could not be dispensed with altogether. But the answer to this question is no longer doubtful, and makes it clear that that practitioner will be at a great disadvantage who does not study the latest evidence on the physiological and therapeutical action of medicines. The growing care in investigating the action of drugs, and, we may add, the growing perfection of chemistry and of pharmacy, have shown that the most specific effects may be produced by drugs which a few years ago were not known to exist—witness the case of pilocarpine, of hamamelis virginica or its active principle hazeline, resorcin, &c. The old physicians used to speak of the effects and uses of opium, but recent chemistry and

occupied themselves with the bodies named hæmatoblasts and with Dr. NORRIS' third or transparent corpuscles of the blood, with the result of showing that they are probably ordinary corpuscles partially deprived of their colouring matter or hæmoglobin. BIZZOZERO has suggested an instrument to which he has applied the name of hæmatocytometer in which the intensity of colour and the degree of opacity are measured by the different thicknesses that must be given to a solution, or to a blood mixture, to reproduce a certain optical effect; the imitation of a test solution for colour and the disappearance of a luminous point situated at a certain distance for the opacity.

Careful observations made by VIGNOL in RANVIER'S Laboratory seem to have demonstrated that in the lower vertebrata the heart possesses a local motor and a local inhibitory centre.

DUCLAUX has written a work on ferments and their relation to disease. In this he treats of the nutrition and development of microscopic organisms, and gives some remarkable facts bearing on their growth. Thus, in the case of the *aspergillus* a sixteen hundred thousandth of nitrate of silver is sufficient to arrest its growth, whilst it will not grow in a vase of silver, though the quantity of metal dissolved is totally inappreciable to chemical tests.

The obscure subject of the dilatation of the bloodvessels under the influence of the nervous system has been treated of at great length and with much ability by MM. DASTRE and MORAT, who have satisfied themselves that it is in most, if not in all, instances of a reflex character, the centre being in the spinal cord and medulla oblongata, the sensory being the afferent and the sympathetic nerves containing the efferent fibres, which directly induce the dilatation, and which emerge from the cord by the anterior roots of the spinal nerves, and then associate themselves with the sympathetic.

DUBAR and REMY have studied the phenomena of absorption by the peritoneum, and have shown that albumen in solution is absorbed by the peritoneum without producing apparent change in that membrane, that the albumen so absorbed does not accumulate in the serum of the blood, and that it is well borne and inoffensive. They have further endeavoured, by means of the injection of colouring agents, to follow the course of the absorbed material. The histology of the mammalian gastric glands and the relation of pepsin to the granules of the chief cells has been worked out by LANGLEY with much success.

HONIGSBERG has compared the digestibility of meat in various conditions in artificial gastric juice, and finds that with an artificial gastric juice composed of five grammes of WITTE'S pepsin, dissolved in 1000 cubic centimetres of water acidulated with one part of hydrochloric acid, raw meat yields 39.7 per cent. of peptone, boiled meat 26.6 per cent., and roast meat 48.0 per cent. The action in the stomach itself is undoubtedly far more complete, but the experiment is in favour of the digestibility of well-roasted meat. SCHULZE and BARBIERI have demonstrated the presence of peptones in the juices of various plants, as in the potato and beet.

VELLA has made intestinal fistulæ, and then injected pilocarpine subcutaneously, which he finds possesses a remarkable power of inducing secretion of the intestinal juice.

Experiments made with the juice so obtained emulsify fats, converted cane sugar into grape sugar, and digest proteids. It acts, however, differently from gastric juice. Gastric juice dissolves the perimysium first, then the primitive fibre; whilst intestinal juice attacks the fibre first, and leaves the perimysium intact.

GOLTZ has continued his researches upon the brain, and shows that injuries of a severe character to the (convolutions) of the brain in dogs produce no diminished intelligence, but a remarkable change in psychical character, harmless and good-tempered dogs becoming snarling and morose; whilst, if the occipital lobes are damaged, the animals preserve their good-temperament, but their intelligence becomes much more impaired.

MERSCHESKI has experimented on the function of the olivary bodies of the medulla oblongata, and has shown that after deep injuries to them rolling movements towards the injured side occur with nystagmus of the corresponding eye. He believes that they stand in close relations with the functions of the cerebellum. The structure of muscle has been investigated by HIPPOLYTE MARTIN, who shows that the muscular fibril is composed like an amoeba or leucocyte of granular protoplasm, but affected with cylindrical rods, in which the proteic granules are of several species, and arranged in a determinate order. The dark discs are composed of two closely apposed granules, the extremities of the rod, and the space between them is occupied by three other granules, the centre one being larger than the other two; in moderate contraction the three granules appear fused together, whilst in full extension they appear as separate granules.

The duration of the latent period of the "tetanus" in the healthy adult has been carefully studied by EULENBERG in healthy adults, and found to be on an average little more than 2-62 of a second. He regards it as more than a mere reflex phenomenon, and endeavours to prove that it is of a complex nature. Death appears, on the other hand, disposed to regard it as a contraction.

A very complete treatise has been published on the physiology of the muscles and nerves by M. RICHET, who gives in a remarkably clear and orderly manner the facts that are at present known in regard to the important lesions, which M. RICHET has endeavoured so much to elucidate.

We must not omit to mention that Professor SANDERSON has been offered, and has accepted, the vacant post of Professor of Physiology at Oxford. We trust he may long continue to occupy that office, we hope also that he will exert his influence in the foundation of a good medical school, and gather around him a band of youthful workers, who may enable Oxford to vie with the universities of the Continent.

#### Pathology.

In the department of pathology the year has been, on the whole, infertile. Isolates have been reported in their usual abundance, and a few of new discoveries there have been few,

signal exception, of small importance. The year has been especially barren so far as English pathology is concerned. From the laboratories of neither England nor Scotland has any important work proceeded, and even from the good Brown Institution, from which we have had such a rather work in the past, comes the sound of physiology of pathology. The lectures on Inflammation by Dr. BURDON SANDERSON, and on Pulmonary Cavities by Dr. EWART, deserve, however, especial mention, although, in the former, we are not carried far beyond our previous stand point. Abroad, bacteria still absorb the brilliancy of the pathologists of Germany and France, and the word "investigation" has been sufficiently attested by the have of the literature of pathology. Few recent discoveries of the tubercle bacillus, for which KOCH certainly deserves the high credit he has received, although the discovery had been worked out by many investigators, and was made independently to him by BAUMGARTEN. The organisms of tubercle have given us a new pathologists in all countries abundant work, and its practical application has been made in a few cases. In the new facts of the pathology of the tubercle, in addition to the technical facts regarding observation which have been abundantly supplied by other departments of bacterial pathology some have been supplied, fewer in number, however, during years. Among them may be mentioned the researches of BIRCH-HIRSCHFELD on the association with syphilis, and of KEATING on the lesions, although the latter are scarcely more than a confirmation of the half-forgotten observations of VACHERWOOD. Of especial significance also is the fact by FEHLEISON, that the organisms of erysipelas of giving rise to the disease after their separate The remarkable observations of LAVERAN on the malarial parasites which apparently constitute the active agents in the production of malarial disease, have been confirmed by RICHARD, and may perhaps attract more attention than they have hitherto received. In other specific diseases the chief researches are those of POPOFF on the changes in the blood in typhoid fever, and those of EISENBERG on the alterations which are produced in the salivary glands by the malarial parasites. In the region of general pathology, the subject of inflammation has been little studied. Besides the lectures of BURDON SANDERSON, already alluded to, the most important researches are those of SPINA, on the morphological changes presented by protoplasmic elements in the tissues, which have not the form of cells. ZUNTZ has investigated the cause of the increased oxidation which occurs in pyrexia, and believes that the facts he has ascertained regarding the action of curara must, to some extent, alter our views of the process. The subject of septicæmia has been somewhat neglected during the past year, and the work which has been done only serves to show how much more is needed. The experiments of ROSENBERGER, for instance, suggest that the relation of bacteria to this condition may be secondary and not primary, and are of special interest in connexion with the facts which ROSSBACH has published, which apparently prove that, under certain circumstances, the organisms always present in the body may be the source

of those associated with septicæmia. The general pathology of the blood has attracted little attention, nor can we expect new facts until there is more agreement regarding its constituents. We must not, however, omit to mention the researches of HAYEM on the processes by which hæmorrhage is arrested, and on the peculiar "hæmatic crises" which occur during the course of many acute diseases. Apart from the question of its relation to bacteria, the pathology of tubercle has been the subject of many researches, and among those which deserve mention are that of CHIARI on the hyaline metamorphosis which tubercle undergoes; the laborious investigations of ARNOLD on the minute structure of tubercle in various organs; the studies of its formation in the thoracic duct by STILLING, and in the veins by WEIGERT, and in the synovial sheaths of tendons by TERRIER and VERCHÈRE. The facts described by TAPPEINER regarding the production of phthisis in dogs by the inhalation of tuberculous sputum have been confirmed by WEICHELBAUM, although no new evidence of the contagiousness of phthisis in the human subject has been adduced. The observation of FRIEDLANDER may be regarded as demonstrating the frequent occurrence of organisms in connexion with croupous pneumonia, although it still leaves undetermined their precise relation to the disease. The etiology of gastric ulcer has been studied experimentally by AUFRECHT; the cause of the jaundice of newly born children has been investigated in a most able and thorough manner by BIRCH-HIRSCHFELD. No observations on the gastro-intestinal tract are more important than those of NOTHNAGEL on intestinal catarrh and atrophy, which, although undertaken from a clinical standpoint, are of great pathological interest. The occurrence of compensatory hypertrophy of the kidneys has been demonstrated by RIBBERT; and the researches of AUFRECHT have thrown considerable light on the pathogenesis of renal cirrhosis. Lastly, in what may be termed toxicological pathology, the most important investigations have been those of CORNIL and BRANLT on the effects of arsenic and phosphorus, which have shown the identity of the changes produced by the two agents.

#### Therapeutics.

In the department of therapeutics there are many indications of vitality and of distinct reaction from that of scepticism as to the use of medicine which followed, as effect follows cause, the rise and fall of homœopathy. The demonstration afforded by this exploded system, in its simplicity, of the strong recuperative powers of the system, naturally led physicians to question whether medicine could not be dispensed with altogether. But the answer to this question is no longer doubtful, and makes it clear that that practitioner will be at a great disadvantage who does not study the latest evidence on the physiological and therapeutical action of medicines. The growing care in investigating the action of drugs, and, we may add, the growing perfection of chemistry and of pharmacy, have shown that the most specific effects may be produced by drugs which a few years ago were not known to exist—witness the case of pilocarpine, of hamamelis virginica or its active principle hazeline, resorcin, &c. The old physicians used to speak of the effects and uses of opium, but recent chemistry and

therapeutics have resolved opium into nearly a dozen substances with entirely distinct physiological effects, and capable of the most various use in the hands of the physician. This year has witnessed the introduction of a substance not originally in opium, but resulting from the action of hydrochloric acid on morphia—apomorphia. Few of the books on *materia medica* published this year contain any notice of it. Its use—for the discovery of which the profession is indebted to Dr. GEE—is that of an emetic to be introduced hypodermically. But it is in the smallest quantity powerfully effective—witness the remarkable case of brandy poisoning reported by Dr. AMAND ROUTH in THE LANCET of last week. The hypodermic use of quinine in ague has been shown in our columns by Professor CHARTERIS of Glasgow, and Dr. GEORGE RANKINE of the 6th Bengal Cavalry. The stimulating effect of fifteen minims of rectified ether administered hypodermically, and repeated, seemed to determine a favourable issue in a case of aconite poisoning detailed by Mr. CECIL A. COOKE. The hypodermic administration of the active principles of purgatives does not promise to supersede the ordinary use of laxatives. The antidotal action of the alkaline sulphates in poisoning by carbolic acid was illustrated by a case in the Royal Southern Hospital, reported by Mr. T. D. RANSFORD. Though some antiseptics are themselves shown to be capable of serious poisonous effects, the antiseptic and germicide theory still dominates therapeutics, not only in surgery but in medicine. Our pages are full of letters and other communications from practitioners alleging the efficacy of some antiseptic or other in zymotic cases. The local use of boracic acid dissolved in glycerine and water in diphtheria, by Mr. T. D. HARRIES, of Aberystwith, is a case in point. (See THE LANCET, Feb. 25th, 1882.) His conclusions are confirmed by cases reported by Dr. GOODHART to the Clinical Society, though he does not seem to have been aware of Mr. HARRIES'S clear experience. Another case in point is the use of enemata of carbolic acid in typhoid by M. RAMONET; and yet others, are the successful administration of salicylate of soda in scarlet fever by Mr. JAMES COULDREY, of Scunthorpe, near Brigg, where the disease has prevailed in a severe form, and the use of salicylic acid in typhoid by M. VULPIAN, reported to the Académie Médicale. The use of salicin and salicylates in acute rheumatism was the subject of a most elaborate series of papers, elsewhere alluded to, before the Medical Society. We can only here say that these remedies emerged from the discussion with enhanced reputation. It is noticeable, however, that Dr. HERBERT DAVIES still prefers the blister treatment. The report of the committee of the Clinical Society on Rheumatic Hyperpyrexia, though chiefly clinical in its bearings, affirms the value of the prompt and early use of cold. The therapeutics of intestinal obstruction, not due to coarse mechanical conditions, are advanced by experience of the action of hyoscyamine in a case reported by Mr. KENNETH MILLICAN, and by a growing use of belladonna, in cases where opium has failed or is contra-indicated. For the production of anæsthesia there is an increasing preference for ether as an alternative to chloroform. The action of drugs and the best mode of administering them are thus becoming more and more questions of the first importance

in medical education and practice, in connexion with other great branch of therapeutics—the proper management of the sick—which is receiving at present much attention.

#### Surgery.

THE records of surgery during the past year are marked by any striking novelty or great progress, nevertheless good work has been done in many directions. Sir HENRY THOMPSON has recorded instances of removal of tumours of the bladder through perineal incision; and he advocates an exploratory incision in cases where the diagnosis is doubtful. He has also another list of 101 cases of lithotripsy to the already number recorded by him. Calculi have been removed from the kidney through a lumbar incision by Mr. BECK, Mr. BUTLIN, and other surgeons have recorded cases in which the kidney was examined with a needle through a lumbar incision without discovering a calculus. It has been shown that this operation is practically safe. A considerable number of nephrectomies have been recorded by surgeons at home and abroad; and a lively discussion at the Societies has shown that much interest is felt in the question as to when a splenectomy should be undertaken in cases of allied subject—i.e., splenectomy in cases of l. l. l. has been discussed by Mr. HERBERT COOKE. WARRINGTON HAWARD; the argument of the present to be conclusive in condemning the operation. Numerous facts in abdominal surgery, which tend to differentiate our art seems to be gradually (regrettably) separating from the field of abdominal surgery will therefore leave the discussion of oophorectomy, and other performances, the which are dreadful, for mention in another paper. Mr. WHITEHEAD'S method of excision of the prostate has been practised and commented upon by several surgeons. There has been some diversity in the opinion, but on the whole we gather it to be a valuable addition to the treatment of prostatic disease. A novelty in the treatment of empyema has been suggested by Mr. R. W. PARKER, to introduce purified air by a second puncture into the thorax, to replace the fluid which has been removed, but little opportunity has at present offered for the test of experience. Mr. DUBLIN tied the innominate artery, and it appeared at the time as if the case were likely to prove successful; but hope was not realised. Mr. HOLMS recorded a case in which the theca vertebralis was injured. Mr. GOTTSALLO and Mr. CLUTTON have again raised the question of the treatment of spina bifida by reporting successful cases in which MORTON'S method had been employed, and the subject has been referred for investigation to a committee of the Society. A very remarkable lecture was given by Sir J. PAGET at the Royal College of Surgeons, on "Some of the New Diseases;" it was the first of an annual series of lectures founded by the widow of the late Mr. BRAUER of Reading, and was equally interesting from its originality and suggestiveness. Three elaborate discourses on matters have appeared in our columns: Mr. MAJORS'S lecture at the Brompton Hospital on "Diseases of the

between the passing of the primary examination for the diploma of member and admission to the final examination, except in certain special cases. In May the report of the Joint Committee on the proposed institution of an examination in elementary anatomy and physiology was presented to the Council. The committee recommended that the proposed examination should be held at the various medical schools, to be conducted by the teachers, instead of at the College. At the meeting held in June it was resolved to call the attention of the authorities of the several recognised schools to the proposed regulation, and to invite the teachers of anatomy and physiology to confer with the Joint Committee at the College as to the mode of carrying out the proposed examination. This conference was held on June 26th, and the principle of holding an elementary examination in anatomy and Physiology at the schools was, after a long and full discussion, almost unanimously adopted, with the condition that six months should elapse between the elementary and the Primary Examinations. On July 6th Mr. MARSHALL and Mr. POWER were re-elected members of the Council, and Mr. CROFT was elected a member of the Council, and in the following week Mr. SPENCER WELLS succeeded Sir ERASMUS WILSON as President of the College, Mr. MARSHALL and Mr. COOPER FORSTER being elected senior and junior Vice-presidents respectively. The vacancy in the Court of Examiners, caused by Mr. RUSSELL's retirement, was filled up in October by the election of Mr. BRYANT. In July Mr. T. M. STONE resigned the post of Clerk, after a useful, valued, and honourable service of fifty years at the College. On the 15th inst. seven delegates were appointed, as hinted above, to meet and confer with a sub-committee of the Royal College of Physicians on the possibility of a combination of the two Colleges for the establishment of a complete conjoint medical and surgical examination. On the 13th Sir JAMES PAGET delivered the first Bradshawe Lecture at the College. On some New and Rare Diseases." This lecture was published *in extenso* in our columns on the 16th inst. It may be mentioned that during the year an attempt has been made to form an Association of Fellows, but as some of the promoters have not hesitated to avow a wilful spirit of antagonism to the College, the attempt has hitherto received no countenance from the principal Fellows.

#### *Army and Navy Medical Departments.*

During the past year no change has taken place in the organisation of the Army Medical Department. At the half-yearly examination for admission into the service a sufficient number of candidates presented themselves to make it really competitive, and to show that the conditions of service at present in force are acceptable to the profession. At the beginning of May Sir WM. MUIR retired from the post of Director-General, and was succeeded by Dr. T. RAWFORD, who was up to that time Principal Medical Officer of the troops in India. His appointment was regarded with much satisfaction by the Department. On the outbreak of the war in Egypt Dr. CRAWFORD was called upon to organise the medical service for the force to be employed there, which he did in a manner that met with the full approbation of the military authorities. When, from unforeseen changes in the military operations, difficulties were

experienced in bringing up to the front those supplies of medicines and medical comforts which had been provided on a liberal scale, an attempt was of course made to show that this was owing to the defective organisation of the Department and the want of foresight on the part of the heads of the medical service. These charges were supported by statements of a very unscrupulous character, and were, we fear, in many instances put forward for the purpose of throwing discredit on the present system of departmental organisation. Many of these statements have already been disproved by the evidence of eye-witnesses, and we have no doubt that the inquiry now being conducted by the Committee appointed by the Secretary of State for War will completely remove the odium which has been attempted so unfairly to be cast upon the medical service. The military authorities, both at home and in Egypt, have borne testimony to the praiseworthy manner in which the medical officers discharged their duties, and the sympathy of their professional brethren in civil life was well manifested by the banquet given to celebrate their return to England on the termination of the war.

An important alteration was introduced into the Indian Medical Service during the year by the adoption of the station hospital system instead of the regimental. This was carried out under the supervision of Surgeon-General CRAWFORD before he left India to take up the appointment of Director-General. The Indian Service furnished the necessary medical staff for the contingent employed in Egypt, and the arrangements were carried out in a most satisfactory manner.

There has been no change in the organisation of the Naval Medical Service during the year. The Order of Knight Commander of the Bath has been conferred on Mr. J. WATT REID, the Director-General of the Department.

It is satisfactory to find that for all the three branches of the public service an adequate supply of candidates has been forthcoming at the competitive examinations; and it is also matter for congratulation that in the distribution of honours for service in Egypt the medical officers have not been left out, as has happened too often in previous wars, but have received a fair share of the promotions and decorations.

#### *Mirror of Hospital Practice.*

Thanks to the generous co-operation of the physicians, surgeons, and their assistants attached to the various hospitals and dispensaries through the kingdom, we have been able to publish in our "Mirror of Hospital Practice" a large number of selected cases, presenting aspects of clinical, pathological, and therapeutical interest. The cases have not only been instructive in themselves, but have afforded a tolerably accurate indication of the progress of medicine and surgery. Out of the records many examples may be found of things both "rare and new." Where every case presents some interest it is difficult to select instances for special mention. Among the medical cases we may, however, cite:—rupture of lung, pneumothorax, paracentesis, recovery, under the care of Mr. GOULD at Westminster Hospital; hydronephrosis treated by aseptic incision by Dr. TUCKWELL and Mr. H. SYMONDS, of the Radcliffe Infirmary, Oxford; spontaneous rupture of the heart, under the care of Dr. COUPLAND, of the Middlesex Hospital; ulcerative endo-

Paris, has been commenced, and is well supported. The Ophthalmological Society has held its meetings with regularity under the able guidance of Mr. BOWMAN. The genial manners, the large views, and vast experience of Mr. CRITCHETT, who would probably at no distant date have succeeded Mr. BOWMAN in the presidential chair, and whose death the members of the Society deplore, will be long held in remembrance. The histology of the optic nerve has been studied by Dr. BERGEN, who has been unable to discover the direct communication observed and described by LEBER, between the capillaries of the optic nerve and of the choroid. ROBINSKI has investigated the structure of the lens; AEBY, the histology of the canal of Petit, and the Zonule of Zinn; PREISS, the lymphatics of the cornea; WOLFF, the nerves of the cornea; HEISRATH, the drainage system of the anterior chamber of the eye. CHARPENTIER has contributed some papers on the differential sensibility of the eye, and he, JAEGER, MAGNUS and others have written on the sense of colour. The use of the spray in operations on the eye seems to be spreading both in France and Germany. It will probably prove useful in cases of enucleation and abscission, but it is not well adapted for cataract operations nor for iridectomy. Many papers have been published on purulent ophthalmia, notably those of HAUSSMANN, ABADIE, BAILLY, and DE WECKER, and evidence appears to be accumulating that cases of blennorrhoeic and gonorrhoeic ophthalmia, and of suppurative keratitis, are in many instances attributable to, or, at least, are associated with the presence of, certain micrococci and spores of fungi, such as the aspergillus, a subject that has been well worked out by LEBER of Berlin. The employment of homatropin as an agent capable of effecting dilatation of the iris, without the persistent effect of atropin, has come into general use, and pilocarpine has been shown to be not only a valuable and effective remedy in various diseases of the eye, but that it is an excellent antidote to the effects of atropine. KNAPP has collected a series of interesting cases in which foreign bodies have been tolerated in the fundus oculi, showing that it may not always be requisite in such accidents to proceed at once to enucleation, especially if the foreign body be small. FEDOR KRAUSE has given a good account of the pathological changes occurring in sympathetic ophthalmia, showing that the changes proceed chiefly along the ciliary nerves. Dr. AYRES has written a paper on the same subject, recording cases which seem to show that the changes are progressive along both the optic and the ciliary nerves. But the number of memoirs and original communications on the pathology and treatment of diseases of the eye is immense, and furnishes sufficient evidence of the attractiveness of the diseases of the eye as an object of study.

#### *The Royal College of Physicians.*

AT the Royal College of Physicians several important questions both of policy and ethics have been discussed. One recent and significant act of the College has been to appoint a sub-committee to confer with delegates of the College of Surgeons with a view to the formation of a Conjoint Board consisting only of these two bodies, leaving out the Apothecaries' Society. In this course the College is only accepting a proposal originally made by the College of

Surgeons in May, 1881. The prospect of legalising the movement less opportune and important. A worthy step the College has taken throughout the agreeing to the moderately worded resolution with regard to homœopathy. The report on the however, which appeared in our columns, led to self-assertion of dignity on the part of the College. Whether from the observance of excessive prudential a jealous regard for its fancied importance, it is that henceforward the proceedings of the College considered as private communications. Considered for some years past the proceedings have been unless an intimation to the contrary had been given by the President, the action taken by the Censors must be a retrograde one. Another important question, the College has given an uncertain sound, has been professional advertising. It need only be said that the London College was content with reprobating the extensively advertising, the Irish College advertising of medical publications in the literature. There can be little doubt that if the Royal College of Physicians advertise their business they do a great injustice to the bulk of practitioners whose patients they entice to the consulting rooms. The Irish Fellows in this respect shown a higher sense of justice and less greediness than representatives of the London College. It may be noted—namely, that the College has been obliged to appoint examiners in Anatomy and Chemistry outside the circle of its Fellows. The Gulstonian Lectures of the year were delivered by W. EWART, "On Pulmonary Cavities; their Origin and Repair." The Lumleian Lectures, by Dr. SANDERSON, treated of Inflammation; whilst Dr. FAYRER, in the Croonian Lectures, took the Fevers of India for his subject. The Bradshaugh Lecture was delivered by Dr. E. LONG FOX: "On the Sympathetic System in Disease."

#### *The Royal College of Surgeons.*

The year has been an eventful one for the Royal College of Surgeons. Beginning with the extended examination in Medicine and the new examination in Midwifery for final membership, and ending with the appointment of a sub-committee of the Royal College of Physicians, to consider the possibility of establishing a complete conjoint medical and surgical examination, the year has been full of incidents affecting not only the College, but also the interests of medical education. At a meeting held on January 12th the principle of a scientific examination was approved, on the condition that such examination should be passed before the completion of the professional curriculum. In March a standard was adopted that a candidate referred on the primary examination for three months, should before re-examination produce evidence of having pursued his anatomical and physiological studies during that period to the satisfaction of his teachers, whereas candidates referred for six months, in addition, produce evidence of having dissected a certain number of subjects. In April the Council adopted the proposal, after October, 1882, an interval of two years

between the passing of the primary examination for the diploma of member and admission to the final examination, except in certain special cases. In May the report of the Joint Committee on the proposed institution of an examination in elementary anatomy and physiology was presented to the Council. The committee recommended that the proposed examination should be held at the various medical schools, and conducted by the teachers, instead of at the College. At the meeting held in June it was resolved to call the attention of the authorities of the several recognised schools to the proposed regulation, and to invite the teachers of anatomy and physiology to confer with the Joint Committee of the College as to the mode of carrying out the proposed examination. This conference was held on June 26th, and the principle of holding an elementary examination in Anatomy and Physiology at the schools was, after a long and full discussion, almost unanimously adopted, with the condition that six months should elapse between the Elementary and the Primary Examinations. On July 6th Mr. MARSHALL and Mr. POWER were re-elected members of the Council, and Mr. CROFT was elected a member of the Council, and in the following week Mr. SPENCER WELLS succeeded Sir ERASMUS WILSON as President of the College, Mr. MARSHALL and Mr. COOPER FORSTER being elected senior and junior Vice-presidents respectively. The vacancy in the Court of Examiners, caused by Mr. BIRKETT's retirement, was filled up in October by the election of Mr. BRYANT. In July Mr. T. M. STONE resigned the post of Clerk, after a useful, valued, and honourable service of fifty years at the College. On the 14th inst. seven delegates were appointed, as hinted above, to meet and confer with a sub-committee of the Royal College of Physicians on the possibility of a combination of the two Colleges for the establishment of a complete conjoint medical and surgical examination. On the 13th Sir JAMES PAGET delivered the first Bradshawe Lecture at the College "On some extension in our columns on the 16th inst. It may be mentioned that during the year an attempt has been made to form an Association of Fellows, but as some of the antagonists have not hesitated to avow a wilful spirit of the College, the attempt has hitherto received no countenance from the principal Fellows.

*Army and Navy Medical Departments.*  
During the last year no change has taken place in the organisation of the Army Medical Department. At the half-yearly examination for admission into the service a sufficient number of candidates presented themselves to make it really competitive, and to show that the conditions of service at the beginning of the year are acceptable to the profession. In the beginning of May Sir WM. MUIR retired from the post of Director-General, and was succeeded by Dr. T. CRAWFORD, who was up to that time Principal Medical Officer of the Army. His appointment was regarded with much satisfaction by the Department. On the outbreak of the war in Egypt Dr. CRAWFORD was called upon to organise the medical service for the force to be employed there, which did in a manner that met with the full approbation of the military authorities. When, from unforeseen changes in the military operations, difficulties were

experienced in bringing up to the front those supplies of medicines and medical comforts which had been provided on a liberal scale, an attempt was of course made to show that this was owing to the defective organisation of the Department and the want of foresight on the part of the heads of the medical service. These charges were supported by statements of a very unscrupulous character, and were, we fear, in many instances put forward for the purpose of throwing discredit on the present system of departmental organisation. Many of these statements have already been disproved by the evidence of eye-witnesses, and we have no doubt that the inquiry now being conducted by the Committee appointed by the Secretary of State for War will completely remove the odium which has been attempted so unfairly to be cast upon the medical service. The military authorities, both at home and in Egypt, have borne testimony to the praiseworthy manner in which the medical officers discharged their duties, and the sympathy of their professional brethren in civil life was well manifested by the banquet given to celebrate their return to England on the termination of the war.

An important alteration was introduced into the Indian Medical Service during the year by the adoption of the station hospital system instead of the regimental system. This was carried out under the supervision of Surgeon-General CRAWFORD before he left India to take up the appointment of Director-General. The Indian Service furnished the necessary medical staff for the contingent employed in Egypt, and the arrangements were carried out in a most satisfactory manner.

There has been no change in the organisation of the Naval Medical Service during the year. The Order of Knight Commander of the Bath has been conferred on Mr. J. WATSON REID, the Director-General of the Department.

It is satisfactory to find that for all the three branches of the public service an adequate supply of candidates has been forthcoming at the competitive examinations; and it is also matter for congratulation that in the distribution of honours for service in Egypt the medical officers have not been left out, as has happened too often in previous wars, but have received a fair share of the promotions and decorations.

#### *Mirror of Hospital Practice.*

Thanks to the generous co-operation of the physicians, surgeons, and their assistants attached to the various hospitals and dispensaries through the kingdom, we have been able to publish in our "Mirror of Hospital Practice" a large number of selected cases, presenting aspects of clinical, pathological, and therapeutic interest. The cases have not only been instructive in themselves, but have afforded a tolerably accurate indication of the progress of medicine and surgery. Out of the records many examples may be found of things both "rare and new." Where every case presents some interest it is difficult to select instances for special mention. Among the medical cases we may, however, cite:—rupture of lung, pneumothorax, paracentesis, recovery, under the care of Mr. GOULD at Westminster Hospital; hydronephrosis treated by aseptic incision by Dr. TUCKWELL and Mr. H. SYMONDS, of the Radcliffe Infirmary, Oxford; spontaneous rupture of the heart, under the care of Dr. COUPLAND, of the Middlesex Hospital; ulcerative endo-

carditis simulating typhoid fever, under the care of Dr. STURGES, of the Westminster Hospital; rupture of liver, thrombosis of the hepatic veins and embolism of a branch of the left pulmonary artery, under the care of Mr. MAKINS at the Seamen's Hospital, Greenwich; rupture of an aneurism of the basilar artery, under the care of Mr. C. J. WRIGHT of the Leeds Public Dispensary. Among the surgical cases may be mentioned:—transfixion of neck by a walking-stick, under the care of Mr. DAVIES COLLEY, of Guy's; adherent stone in the bladder, forming after injury to spine, under the care of Mr. HENRY SMITH, of King's College Hospital; successful removal of large uric acid stone, weighing eight ounces, by lateral lithotomy, under the care of Dr. UNDERHILL, of Guest Hospital, Dudley; compound dislocation of the sixth from the seventh cervical vertebra without fracture, under the care of Dr. WHIPHAM, of St. George's Hospital; dislocation of the fifth cervical vertebra, reduction and recovery, under the care of Mr. CEELEY, of the Royal Bucks Infirmary. Among the curiosities may be mentioned a case of eyelashes in the anterior chamber of the eye, the result of a stab, treated by Mr. WILLIAMSON, of the Newcastle-on-Tyne Infirmary, and a fish-hook successfully removed from the œsophagus by Dr. GOLDSMITH, of the Bedford General Infirmary; excision of the pyloric end of the stomach for carcinoma by Mr. SYDNEY JONES, of St. Thomas's Hospital.

#### *The Medical Societies.*

At the various medical societies of the metropolis the year has not been very eventful. There have been no great debates or stirring controversies, but there has been the same steady pursuit of science in the records of cases of disease, of the results of operations, of pathological research, and in the general routine of useful work that renders the meetings of these bodies so attractive and fruitful. Commencing as usual with the Royal Medical and Chirurgical Society, we find this old-established and somewhat conservative body becoming alive to the fact that for some reason or other its meetings were losing much of their former popularity. In point of numbers the Society was never richer, but yet the Fellows failed to appear at the meetings and share in the debates, the contributions even became scanty, and rumour ran that the Society's younger rivals were pressing it rather hardly. However this may be, the changes that have been introduced—minor as they are in importance—during the past few months may have considerable effect in increasing the attendance and interest in the Society's meetings. Professor J. MARSHALL succeeded Dr. BARCLAY in the presidential chair, and his first duty on taking office was to move an address of congratulation to Her Majesty on her providential escape from the attempt on her life. The papers read before the Society have, many of them, led to animated debate, and some have enunciated new principles that may become established. As in other Societies, so here, surgery predominated, Mr. BRYANT relating his successful case of Colectomy for Cancer, a subject expanded more fully in the recent paper contributed by Mr. TREVES on Resection of Portions of the Intestine. Sir H. THOMPSON contributed a successful case of Removal of a Tumour of the Bladder by Perineal Section, and the same surgeon will shortly communicate another paper on this subject to the Society. Mr. HENRY MORRIS's paper

on Dislocation of the Hip-joint was another which aroused discussion, and so did Mr. PARKER's proposal to employ intra-thoracic injection of air as an aid to the evacuation of certain forms of empyema. Other papers, of a more elaborate nature, were the researches of Drs. RINGER, SAINSBURY into the action of Soda and Potash Salts, of Dr. CHAMPNEYS into the production of Mediæ, of Dr. EMPHYSEMA following Tracheotomy, and that of Dr. WAI upon the Postures of the Hand as indications of Action. Sir JAMES PAGET also contributed a paper on cases of the remarkable condition to which the name Osteitis Deformans. One of the cases referred to above has consisted in the exhibition of mineral and other specimens collected from various sources in illustration of the subject of the evolution of life, that way demonstrations of bacterial organisms, and specimens of cranial and cerebral disease, of epilepsy, and of forms of intestinal stricture, have been taken place, adding much to the interest of the meetings.—The Pathological Society has managed to deal with more subjects than occurred at the previous session; the specimens are so numerous that the communications accompanying them are often so terse, that not only is much work got done, but also, we fear, there is less actual debating than in former years. This is to be regretted, for not seldom interesting facts are brought out by discussion. It is pleasing to observe that the Society is receiving more contributions in comparative pathology, owing to the facilities afforded by the Zoological Society to members of the former body in making post-mortem examinations upon animals. We look forward to valuable information being thus furnished to pathologists, and cannot forget that Dr. CRISP, whose death it took place, was the pioneer in this special department in the Society. By the death of Dr. PEACOCK the Pathological Society lost a former President, and the most constant contributors to its Transactions.—In connexion with the sister Society—the Clinical—it is fitting to mention that the revered physician whose loss is fresh in the memory, Sir THOMAS WATSON, was for fifteen years occupant of the Presidential chair. The Society has now a well-established position, and many valuable communications. Amongst the more particularly discussed within it during the past year were Nephro-lithotomy in papers contributed by BECK, BUTLIN, and HAWARD; Nephrectomy by Dr. HART and Mr. GOLDING-BIRD, Dr. BARLOW, Mr. GODLEE, Mr. MARSH and Mr. J. E. ADAMS; subjects in abdominal surgery—e. g., splenectomy, HAWARD, and abdominal section for intestinal obstruction by Mr. GODLEE, deserve prominent mention. The growing boldness of surgeons in the treatment of Myxœdema—a condition which still continues to excite clinical inquiry—was roughly discussed at this Society early in the year. An elaborate Report upon Hyperpyrexia in Acute Erythematism was presented by a Committee of the Society, it dealt exclusively with the clinical aspect of the condition, the Committee not attempting to frame any theory upon its pathogeny.—The chief subjects debated

re can be little doubt, but of the expediency of his action there can be little doubt also. In the spring public indignation was aroused by an attempt on the life of the QUEEN by a man named MACLEAN. MACLEAN was arraigned for high treason, and was acquitted on the ground of insanity. MACLEAN had been in a lunatic asylum, and there never was from the first any doubt as to the unsoundness of mind. It was a clear blunder to go through the farce of a trial, and thus give a notoriety to the case, which would prove an incentive to lunatics of a similar class to imitate MACLEAN's action.

*The Brighton Corporation and THE LANCET.*

Early in the year we had occasion to question the perfect state of the sewerage of Brighton—a course which gave great offence to the Town Council, who commenced an action for libel against THE LANCET. They, however, selected Sir J. BAZALGETTE to report on the sewerage system, and Dr. RICHARDSON on the sanitary condition of the town. These reports agreed in the main with our pictures on the imperfect system of drainage. The Corporation, after the publication of Dr. RICHARDSON'S report, with commendable discretion, retired from the contest. Thus the liberty of the press was vindicated. If we do not discuss (which we do every week) the sewerage or insanitary state of a town, one great function of THE LANCET will be paralysed. Our aim and mission is to diffuse scientific knowledge throughout the world, and to reform local abuses. The amount of good accomplished by the Brighton agitation is simply incalculable. Every health resort throughout the kingdom had its sewage overhauled and its pestilential spots purified. Perhaps the authorities expected a visit from one of our commissioners. But as it is we congratulate ourselves and the Town Councils who have "put their houses in order."

*Public Health Questions.*

The year which is now passing away has, on the whole, been a healthy one at home. In England and Wales the general mortality, so far as it can be ascertained at this date, has been decidedly below the average. A comparatively mild winter led, in the first quarter of the year, to one of the lowest death-rates which has been recorded since civil registration was established in 1837. In the metropolis itself, however, an exceptional fatality from almonary affections amongst persons over sixty years of age was brought about by the density of the prevailing fogs. Throughout the year the prevalence of small-pox has been diminishing. In the metropolis, indeed, the small-pox death-rate is decidedly below the average for the ten preceding years, but several severe outbreaks have occurred in the provinces. It is a matter of experience that a London small-pox epidemic is always followed by an extension of the disease to some at least of the other large towns and ties, and the only peculiarity of the last epidemic is that its extension was longer in showing itself than usual. Amongst the English provincial towns that have most suffered are Bolton, Gateshead, Hull, Leeds, Lincoln, Newcastle-upon-Tyne, Nottingham, Rochdale, and Wednesbury. The mortality from the several continued fevers has also been below the average. In some parts of the kingdom isolated outbreaks have, however, occurred, and of these

the epidemic of enteric fever at Bangor has been by far the most extensive. During the four months June to September over 550 cases of this disease occurred in Bangor and its immediate neighbourhood, the outbreak being one of the most severe which has been recorded in this country within recent years. A searching inquiry was made into the circumstances of the epidemic by Dr. FRED. W. BARRY, the newly appointed Medical Inspector to the Local Government Board, and it was proved that the outbreak had in the first instance been brought about by the contamination of the water-service into which the specifically poisoned excreta of an isolated case had been conveyed by faulty means of drainage, and that its extension was in the main the result of an ill-ventilated system of sewers which facilitated the entrance of the then fever poisoned drain air into dwellings. The long continuance of the epidemic was also favoured by the failure of the sanitary authority at once to act on the recommendations of Dr. BARRY and of their own officer of health. The occurrence of small outbreaks of typhus fever in several large centres of population, and especially in Liverpool, London, and Sunderland, naturally led to the fear that, with the colder weather and the resulting overcrowding in the ill-constructed and ill-ventilated tenements of the lower classes, some epidemic prevalence of that disease might be anticipated. Although, however, more than the usual interval between epidemic prevalences of this disease has elapsed since the last typhus visitation, we are fortunately still without any indication of its further spread. Scarlet fever has, like the continued fevers, been distinctly less prevalent than usual, but in several parts of the kingdom local outbreaks of considerable magnitude and severity have occurred. Amongst the larger towns Accrington, Gloucester, Merthyr Tydfil, South Shields, Oxford, Nottingham, and Hull may be named as having specially suffered; the outbreak in Hull being a continuance of an epidemic which in 1831 caused as many as 682 deaths. The disease has also been fatally and persistently prevalent in several smaller places, such as Worksoy, and also at Upwell, a village near Wisbeach. Diphtheria has throughout the year caused an excessive mortality, the excess increasing as the year has progressed; and in some places, such as Folkestone, Taunton, Sutton-in-Ashfield, Lynn, and Whitstable, there have been marked epidemic outbursts of the disease. We are unfortunately still ignorant of the conditions essential to the development and, to some extent, to the spread of this affection, and with a view of acquiring further information as to its etiology, both the Local Government Board and the British Medical Association have instituted a series of detailed inquiries, the results of which may, it is hoped, hereafter give some indication as to how the diphtheria mortality may be lessened. Both whooping-cough and measles have prevailed to an unusual extent, and some of the measles epidemics have been very fatal. So long, however, as attacks of these diseases are regarded by the ignorant as necessary to the period of childhood, so long must they lead to a large number of preventable deaths. The periodic prevalence of autumnal diarrhoea has been less marked this year than usual, and it is evident that a comparatively cool autumn has in part conduced to this result. But it is equally clear that temperature alone does not regulate the extent of diarrhoea mortality amongst infants. The

mission on the Medical Acts, recommending changes in the organisation of the Medical Council and of the licensing boards in the direction long desired by the public and the profession. This Report shows a natural disposition on the part of the Commission to judge the medical authorities generously, but it nevertheless shows equally a perception of the defects of the existing system. Clauses 5 and 6 of Part I. of the Report are as follows:—

“On the other hand, it has been stated in evidence, and especially by witnesses who have been engaged in private tuition, that not only do the diplomas and degrees of these medical authorities imply very different standards of skill and knowledge, but that in some cases the possession of a diploma affords no guarantee that the practitioner holding it possesses a competent knowledge of medicine, surgery, and midwifery. Several distinct causes appear to us to lead to this result, such as the imperfections and low standard of some examinations; the fact that some examinations are injudiciously divided into parts, the first part of the examination of one Corporation being accepted by another, as in the case of the Apothecaries' Hall of Ireland and the Edinburgh Corporations; to which may be added the unsatisfactory manner in which the examiners themselves are in some instances appointed, as appears from the evidence laid before us by the representatives of the two Societies of Apothecaries.”

Other defects in the existing licensing system are brought out. Certain bodies are specially mentioned by the Commissioners, whose examinations, by a notable concurrence of opinion among the witnesses, are considered unsatisfactory. These bodies are the Apothecaries' Societies, the Edinburgh College of Surgeons, and the Glasgow Faculty of Physicians and Surgeons. The system of the Edinburgh College of Surgeons for creating Fellows, which is practically a system of purchase, was brought out in evidence before the Commission, and was little improved by even Mr. SPENCE'S defence of it. Similarly, in regard to the Medical Council, the work it had done was admitted liberally, and its failures were freely implied in the excuses suggested for its not doing better, and in the suggestions for a radical change in its constitution. The main proposals of the Commissioners are:—

“That there shall be one Medical Council. That in each division of the kingdom there shall be a divisional board representing all the medical authorities of the division, whose duty it shall be to appoint a certain number of persons to be members of the Medical Council, to appoint examiners for the divisional board examinations, which alone are to admit to the Register,” &c.

If legislation takes place on these lines, as we have reason to hope it may, there will be a Medical Council of eighteen members instead of twenty-four, and three licensing bodies instead of nineteen. The Council, moreover, will be no longer a weak and talkative body, fighting for the rights of corporations, but “one supreme controlling authority, entrusted with larger powers than those possessed hitherto.” The universities have been much considered by the Commissioners, and their graduates will be exempted from all the examinations of the divisional board but the final one, and this at a small fee.

A deputation of members of the British Medical Association, and others, waited on Lord CARLINGFORD and Mr. MUNDELLA in November, to urge on the Government

the promotion of legislation on the lines of the recommendations of the Royal Commission. Dr. WATERS, gave a history of the arguments and demands and of the efforts of successive Governments. GLOVER spoke from the point of view of a Scot and the holder of a Scotch diploma. Mr. W of Leeds testified to the fact that those who are one division of the kingdom often quickly another. Both Lord CARLINGFORD and the Viscount listened attentively to the deputation, and the subject should have their attention.

In Parliament, excepting answers to questions of less medical interest, there has been little to the session barren beyond precedent. The chief reason about the work of Parliament is that the House has awoke to the absurdity of its own Rules which have served lately so to hinder legislation that the Legislature itself into disrespect.

#### *Medico-Legal Cases.*

The year 1882 has not afforded many cases of exceptional interest in the domain of medical jurisprudence. The humiliating circumstance of the conviction for murder of a member of the medical profession, however, caused the past year to be held in remembrance. The circumstances of LAMSON'S crime were recapitulated, how for the sake of gain he administered aconitia to his brother-in-law in a gelatine capsule, the crime was clearly brought home to him by a series of chemical and physiological tests. The statement which the alkaloid was detected by Dr. STEVENSON will effectually tend to deter miscreants from using this lethal agent. Owing to the public panic caused by this case the Secretary issued circulars to various bodies of opinion as to the necessity or otherwise of a law which regulates the sale of poisons. (The law appointed by the different medical colleges is not that much information was furnished to the Secretary; but as yet no steps have been taken.) Quite recently a woman named TAYLOR, charged with murdering an old woman by the administration of lead. The circumstances were so late in the columns as to make a repetition of them unnecessary. On the last day of 1881 a curious death was made by a man named BROOKS, in which it appears that BROOKS, a somewhat eccentric man, to castrate himself on December 4th, 1879, he falsely alleged that he had been attacked by two men who attacked him. The result of that was that two men (JOHNSON and CLOWES) were sentenced to ten years' penal servitude. On February 1st, 1882, he again attempted to castrate himself, and was arrested. His statement that his injuries had been brought about by others. He died from the effects of heart disease on the 31st, 1881, and his death-bed confession was the liberation of the men who had been convicted. The conviction and execution of GUITEAU of President GARFIELD must be regarded as a sane. That GUITEAU was on the border

883, and we can only wish it a long career of usefulness.

#### Obituary.

The obituary of every successive year seems sadder than the previous ones, though in the case of the present year it includes the names of many whose age and honours were fully ripe. A few selections from our own death record will show what figures have disappeared:—JOHN CLINT SOUTH, F.R.C.S. Eng.; Sir ROBERT CHRISTISON, Bart.; CHARLES ROBERT DARWIN; Professor SCHWANN, of Liege; Dr. GEORGE BUDD, F.R.S.; Sir JOHN ROSE NORMACK, of Paris; Sir EDWARD BURROWES SINCLAIR, of Dublin; T. B. PEACOCK, M.D.; Professor JAMES R. VOOD, of New York; Professor SPENCE, of Edinburgh; Professor ANDREW BUCHANAN, of Glasgow; Dr. ARTHUR L. REID, of Hankow; Dr. CHARLES MOREHEAD, of Bombay; Sir JAMES ALDERSON, M.D. Oxon.; Mr. J. T. FLOVER; Dr. EDWARD PEELE, of Dublin; Mr. GEORGE BRITCHETT; BHOLA NATH BOSE, M.D. Lond., Bengal; Professor GEORGE GULLIVER, F.R.S.; Professor HENRY DRAPER, of New York; Professor WILLIAM PIRRIE, of Aberdeen; Dr. EDWARDS CRISP; Sir THOMAS WATSON, F.R.S.; Dr. EDWARD J. REYNOLDS, the oldest physician in Boston, who graduated at Harvard fourteen years before Sir THOMAS WATSON graduated at Cambridge; Deputy Surgeon-General PEARSE, late and most valued Chief Officer in the Vaccination Department of the North-West Provinces of India. We should want all the columns of the "Annus Medicus" to record the work represented by these names and the names of practitioners in the more laborious fields of private practice, some of them dying, like LYCIDAS, in their prime, most of them at their post, and not a few filling offices of public trust.

#### Conclusion.

Now we leave 1882, wishing our readers all happiness in the coming year and inviting their co-operation in perfecting the art and science of medicine, with which the well-being of mankind is seen to be more and more inseparably connected.

## Annotations.

"Ne quid nimitis."

### PROFESSORSHIPS AT CAMBRIDGE.

HITHERTO the elections to the Professorships in Cambridge have been made, in most instances, by the members on the electoral roll, who consist chiefly of the residents in the University. In future, however, under the new statutes, the elections will be in the hands of Boards, a Board being nominated specially for each professorship before a vacancy occurs, and appointed by the Senate. These appointments have just been made. The Board for the election to the Professorship of Anatomy consists of Professors Paget, Huxley, Flower, Liveing, Newton, Dr. Allen Thomson, Dr. Michael Foster, and Mr. J. W. Clark. The Board for election to the Professorship of Physiology consists of Professors Humphry, Huxley, Sanderson, Paget, Stokes, Drs. Pye-Smith, Mr. Langley, and Mr. Vines. The Board for election to the Downing Professorship of Medicine consists of Sir George Burrows, Professors Paget, Liveing, and Humphry, Drs. F. Farre, Lauder Brunton, and Richard Quain, and Mr. T. P. Main. The Board for election to the Professorship

of Pathology consists of Sir James Paget, Professors Latham, Sanderson, Humphry, and Paget, and Drs. Michael Foster, J. F. Payne, and Gaskell. It will be seen that, with a view to the representation of opinion outside the University, certain of the persons appointed in each instance are persons not resident in the University, and not officially connected with it; and the selections which have been made in conformity with the provision of the statute requiring this will certainly meet the general approval of the profession. The appointment to the Regius Professorship of Physic remains with the Crown. The Professorships of Physiology and Pathology are new Professorships, now first established by the statutes. The appointment to the former will probably soon be made, and the Board will have little difficulty in making a selection in the first instance. An election to the Professorship of Pathology may be expected to follow at no distant period.

### THE NUTRITIVE PROPERTIES OF RICE.

THE increase in the consumption of rice has lately attracted the attention of several men of science in Germany, and amongst other investigations, an attempt has been made by Professor Voit to discover the relative capacity which various forms of nourishment possess of being incorporated into the system. He has drawn up the following table of the percentage which remains in the body, and of that which leaves it:—

	Percentage incorporated.	Percentage which is not retained.
Meat . . . . .	96.7	3.3
Rice . . . . .	96.1	3.9
Eggs . . . . .	94.8	5.2
White bread . . . . .	94.4	5.6
Maize . . . . .	93.3	6.7
Potatoes . . . . .	90.7	9.3
Milk . . . . .	88.9	11.1
Black bread . . . . .	88.5	11.5

According to these results (the *Bremer Handelsblatt* remarks) meat and rice leave the smallest amount of residuum, and occasion the smallest excessive exertion to the digestion, and in fact introduce the minimum quantity of ballast into the human frame. Dr. Köaig, of Münster, considers that the fact of large masses of population living on rice is easily accounted for, and in summing up the information collected upon the subject, Professor Voit remarks that potatoes, when consumed in excessive quantity, fail to nourish the frame effectively, make the blood watery, and render the muscles weak. Apart from the subject dealt with in the table drawn up by Professor Voit, the question of the relative nutritive value of rice and potatoes has been investigated by Dr. König, who is of opinion that if similar quantities of both articles are compared, the former possesses four times the value of the latter in really nutritive properties. It is also remarked that the introduction of rice as a substitute for potatoes is facilitated by the fact that no such variation takes place in its quality as is the case with the potato, which is liable to be materially influenced by the effects of unfavourable weather.

### SLIPPERY STREETS.

THERE are some evils we seem to ignore and nuisances we tolerate apparently on principle, though what principle it is difficult to conjecture. The slipperiness of the London streets has been notorious from times so far past as to be forgotten. Recently, however, the fact has been demonstrated in a fashion peculiarly offensive. The long continuance of miserably wet and foggy weather has rendered the surface of the metropolitan area, as it has made most other surfaces, especially slimy. It is now really a feat in gymnastics to maintain the perpendicular in not a few of

available information as to the causation of this disease is as yet singularly imperfect, and we can only await the results of the exhaustive inquiry which, now for three successive autumns, has been undertaken by Dr. BALLARD, with a view of clearing up at least some of the more difficult sanitary problems connected with this subject. Leicester, Preston, Hull, Gateshead, and York have, as usual, suffered exceptionally from infantile diarrhoea.

During the year the subject of the isolation of the several infectious fevers has received a large amount of attention, and three important reports have been issued on the subject. The first was Dr. THORNE THORNE'S exhaustive report on the Use and Influence of Hospitals for Infectious Diseases throughout the country generally; a report which embodies all the information available on the subject so far as the requirements of sanitary authorities are concerned. The second was Mr. W. H. POWER'S report on the Influence of the Fulham Small-pox Hospital, which went to show, in the most convincing manner, that the aggregation of a large number of small-pox patients in a populous centre was attended with a spread of the disease amongst the surrounding inhabitants. The report was one of the most complete that has ever been issued by any sanitary department. It proved that the diffusion of the small-pox contagion had operated over a wide area; that it had come into operation every time the hospital had been used for the reception of acute small-pox cases; and that, owing to the uniformity of its incidence upon all the surrounding population, quite irrespective of the existence of roads or other channels of human intercourse, the diffusion must necessarily have been communicated through the atmosphere. The circumstances elicited as the result of this investigation led to the appointment of a Royal Commission to inquire into all the circumstances affecting the isolation of infectious diseases within the metropolis, and the report of that Commission formed the third contribution to this important subject. The Commissioners arrived at the conclusion that the metropolitan small-pox hospitals had operated injuriously upon the neighbourhoods in which they are situated; and although not assenting in full to Mr. POWER'S contention that the mischief was brought about by aerial diffusion, yet they would appear to have been largely influenced by this view in so far as their recommendations are concerned. We have so recently commented on this report that we would now only add a hope that legislation will speedily give effect to the conclusions which have been urged upon the Government by the Commission. The deaths by erysipelas following vaccination in Norwich were considered of sufficient importance to demand public inquiry by the Local Government Board, who, in the first instance, appointed Dr. AIRY to investigate the circumstances attending the fatality. Subsequently Mr. HENLEY was associated with Dr. AIRY in the inquiry. The report was so unsatisfactory that Dr. BUCHANAN deemed it necessary to append a memorandum showing that the conclusions arrived at by the inspectors were not borne out by the evidence, and that important considerations which might have led to the elucidation of the cause of the erysipelas had been overlooked.

The Parliamentary session has been very barren in sanitary legislation, and only two statutes call for any notice. One extended the Public Health Act so as to enable sanitary

authorities to make by-laws regulating fruit pickers and their lodgings; the other amended the Artisans' and Labourers' Dwellings Act, and provided means, amongst other things, for the purchase of houses, the demolition of which was necessary for the opening up of alleys, &c. Two other subjects, however, deserve notice in this connexion. During the year the Local Government Board completed their series of model by-laws by the issue of several sets of clauses for the regulation of noxious trades; and the Education Department of the Privy Council in their New Code of 6th March made provision for the issue of grants in the case of schools which, without being closed, may suffer from a attendance owing to the prevalence of infectious diseases, also for requiring school managers to comply with the orders of sanitary authorities as to the closing of schools in the case of epidemics, and for the closing of schools in the case of epidemics, and for the closing of schools in the case of epidemics.

Europe has fortunately escaped from the impact of any Eastern epidemic disease. Plague has, however, prevailed to some extent in Persian Kurdistan, the appearance after an apparent cessation of several years, and the rumours as to the dangers which we run by the introduction of cholera through the Mediterranean have been revived, and the presence of that disease in an epidemic form both in India and in some of the islands bordering the China Sea, led to an attempt to hinder traffic through the Suez Canal at a critical moment of the recent Egyptian epidemic. England, however, distinctly refused to submit herself to the regulations which the Egyptian Government sought to impose, and the result has fully justified the course which she took. It is to be hoped, indeed, that before long some final settlement on a rational basis will be made as to the constant disputes arising with reference to the subject of quarantine, as this antiquated process is understood in Egypt and in some other countries. Following on the Mecca pilgrimage cholera broke out in the Hedjaz and other localities affected by the annual visit to the holy city. At Jeddah the disease still prevailed in the middle of last month, but so far as Europe is concerned, all danger may now be regarded as having passed.

#### Miscellaneous.

A very notable event during the past year has been the opening of the Royal Courts of Justice, and in THE LANCET of November 4th will be found the report of our Commissioner on the sanitary aspects of the new building. The building, although praiseworthy, is by no means above criticism, and it is to be hoped that in the future when Government offices have to be erected some of the suggestions offered by our Commissioner will be acted upon by the Government of the day.

A very laudable attempt to improve the sanitary conditions of ships was made by the Directors of the Orient Line in the construction of the steamship *Austral*, undoubtedly the most magnificent vessel of its class. This ship's career has been most unfortunate, for she was capsized a few days after her departure from Sydney Harbour, owing to the carelessness of the crew in charge during coaling, and although it is hoped that she may be floated again, one cannot but have misgivings as to the difficulties of such a work may prove insurmountable.

The Parkes Museum has been incorporated during the year, and has been removed from University College premises in Margaret-street. It will be opened

as stated by Dr. Macnaughtan, nothing could have been done to avert the fatal consequences of the fall. An event of this kind, from whatever cause arising, must give rise to much anxiety on the part of the responsible officers, and we trust that Dr. Macnaughtan will find only sympathy from those placed over him in the regiment. The principle of non-restraint has been very roughly carried out at Perth, and hitherto with the best results. In no prison with which we are acquainted do the troublesome and often dangerous patients appear to be managed with less of harshness or friction. This is abundantly evidenced by the fact that the strait-jacket has been in requisition during this year; and the care with which Dr. Macnaughtan has brought about this state of affairs renders him specially worthy of support under his present worry.

#### HEALTH OF THE TROOPS IN EGYPT.

THE reports which reach this country of the improvement in the health of the army of occupation in Egypt continue satisfactory, as showing a reduction both of sickness and mortality. It is true that this has not been so rapid as it has been desired, and as many anticipated; but the result of this is too obvious. It has arisen from the impossibility of moving the men sooner into comfortable quarters where due attention could be paid to their health requirements. The buildings handed over to the military authorities for the occupation of the troops were in such a condition that had the men been at once moved into them the probable result would have been an outbreak of malarial disease. The Highland Brigade has at last been moved into them, and we look forward to a more marked diminution of sickness. This anticipation is, we think, justified by the fact that the regiments at Alexandria, which have been in quarters for some time, are stated to be in very good health. The result of the arrangements for sending convalescents, especially the fever cases, a trip up the Nile under the care of the indefatigable Mr. Cook proved very successful, the men returning greatly improved in health. It is stated that Lady Strangford's hospital at Cairo has been found extremely useful, and that steps are being taken to obtain the use of the Ramleh Palace, near Alexandria, as a convalescent establishment.

#### PASTEUR ON RABIES.

AT a recent meeting of the Académie de Médecine, Bouley communicated, in the name of M. Pasteur, a summary of conclusions regarding rabies at which the distinguished investigator has arrived. The first two enunciate familiar truths that the dumb madness and furiousness, and, in short, all varieties of rabies, are caused by the same virus, and that the symptoms of rabies are extremely variable. It is assumed that the characters of the several cases depend on the points in the nervous system at which the effect of the virus is chiefly localised. In the case of rabid animals the virus is associated with several kinds of organisms, and the inoculation of the saliva may cause death in three ways: by means of the special salivary organisms, by excessive suppuration, and by rabies. The fella oblongata of the human subject, as well as that of animals, after death by rabies, is always virulent, and the virus is also found in all parts of the brain, and it persists in the brain after putrefaction has set in. There are two methods of inoculation by which the period of incubation of rabies may be greatly shortened, and the disease produced not only rapidly but with certainty: one is by the injection of the virus into the blood; the other is by trephining the skull and placing the virus in the arachnoid cavity. Rabies then terminates at the end of six, eight, or ten days. M. Pasteur has met with some cases of the "spontaneous cure" of

rabies, but only in cases in which the disease did not develop beyond the initial stage. In such a case, in which the early symptoms passed away, the disease has been known to return at the end of a certain time—as two months,—and then to run the ordinary acute and fatal course. Mention is also made of the cases of three dogs inoculated in 1881: two quickly died from rabies; the third, after manifesting the early symptoms, recovered. The latter animal was inoculated by trephining in 1882 on two separate occasions, but without effect. M. Pasteur asserts that he now possesses four dogs which will not contract rabies, whatever the method of inoculation adopted or the proved virulence of the material employed. These facts he believes to be the first step towards the discovery of a method of the prevention of rabies by its inoculation. He confesses, however, that the end seems to be at present far distant.

#### VENTILATION OF RAILWAYS INTO THOROUGHFARES.

WE have already expressed our strong opinion that it would be incompatible with the interests of public safety to allow the ventilation of underground railways into the streets. The project for the construction of ventilating shafts in Queen Victoria-street, City, is a particularly absurd one, and should be, at once, interdicted. Apart from the obstruction to traffic and the danger of frightening horses thus threatened, it is most undesirable that not only here, but anywhere, special openings should be made in the midst of populous districts through which to discharge the concentrated impurities of a tunnel atmosphere. It would be far better to empower, and compel, the companies to purchase such blocks of surface as can be opened, and to make considerable openings for the escape of gases and vapours by unroofing their tunnels. This would prevent accumulation, instead of simply providing outlets, for the escape of suffocating vapours and gases.

#### THE BRISTOL GENERAL HOSPITAL.

GREAT improvements are in progress at the Bristol General Hospital, especially with regard to the sanitary arrangements of the several buildings. Last week Dr. Davies, medical officer of health for the city, delivered a lecture, in which he explained to a number of students and others the principles on which the drainage of hospital buildings should be carried out. The need for an absolute air-break between all pipes leading from the buildings to the interior of the drains, as also for ensuring a constant current of fresh air through all the drains, was especially insisted on, and the works themselves, which are being executed under the supervision of Mr. Eassie, C.E., were subsequently inspected.

#### MORTALITY AND SICKNESS IN FRIENDLY SOCIETIES.

THE actuary of the Friendly Societies' Central Office having officially reported that the quinquennial returns of sickness and mortality experience furnished for the five years ending 1880, in accordance with the Friendly Societies' Act of 1875, had supplied adequate data for the purposes of that Act, a short Act was passed last session which in future relieves these societies from the duty of furnishing such returns. Mr. Sutton, the actuary referred to, in an appendix to the recently issued report of the Chief Registrar of Friendly Societies thus describes the object for which these quinquennial returns were instituted: to collect from the experience of the societies adequate data from which trustworthy tables may be constructed, with the approval of the Treasury, for the information and guidance of societies. In order to ascertain the duration of sick-pay, as affecting the cost thereof to the society, the form used for the

the more crowded thoroughfares of London. Where the pavements are narrow or slope a little, the attention required to avoid "striking up," as they say of horses, is considerable and annoying. This is a disgraceful state of matters. It is idle to talk of putting the law in force to compel householders to sweep before their doors. Not a few of the worst places are opposite blank walls. Indeed, if one part of a street were thoroughly cleaned it would be quickly smeared with greasy mud brought from other parts, or the roadway; unless, indeed, it should occur to anyone to put the law in force against "authorities" responsible for keeping the streets proper in a passable condition. It is useless to remonstrate; but it ought to be put on record that the pavements and carriage-ways of London are probably at this moment in a more neglected and execrable condition than they have ever before been, despite all the improvements, and in spite of the large sums of money extracted from the pockets of the ratepayers to cleanse away the filth that is allowed to accumulate, and to put an end to the nuisance, which not only remains but increases. Many a sprained ankle, "jarred" spine, and "shocked" nervous system attest the mischievous nature of the nuisance we tacitly tolerate.

#### NEW HUMAN ENTOZOOON.

A FEW weeks back it was announced in our columns that Dr. Patrick Manson, who is now in England, had detected a curious cestode in the human body. He found twelve parasites in the subperitoneal fascia and elsewhere. How they came there is a matter of opinion, but under the name of *Ligula Mansonii* the worm was described by Dr. Cobbold at the last meeting of the Linnean Society. The author of the paper stated that probably the infested Chinese had drunk from a pond frequented by water birds infested by ligules, whose immature stages of growth are passed within the fishes living in the same ponds. Dr. Cobbold alluded to the destructive effects of ligules amongst the tench living in the ponds of La Bresse. He pointed to the circumstance that Italians were accustomed to eat fish-tapeworms under the name of *macaroni piatti*, and he expressed the belief that Dr. Manson's patient had swallowed the ciliated embryophores and their contained proscelices which had thus strayed and bored their way into the man's tissues. It is satisfactory to know that they had no concern in the production of the human victim's death.

#### THE SEWERAGE OF HENDON.

HENDON has for some time past been in difficulties with regard to its sewerage system, and with a view of arriving at some definite decision on the subject, Mr. C. F. Hancock, a member of the Local Board, was recently deputed to obtain all possible information with respect to the various processes of sewage-disposal in operation in this country. Mr. Hancock's report deals with the Lime and the Rivers' Purification Company's processes, with the Irrigation and the Rochdale Pail systems, and with several other methods. After considering them all in more or less detail Mr. Hancock is inclined to recommend for the adoption of his colleagues the system of the Rivers' Purification Company. The grounds for his conclusion are, in the main, that under such a system an effluent can be obtained that will satisfy the conditions of the Rivers' Pollution Prevention Act, 1876, that the company takes all the responsibility in consideration of an annual payment or subsidy, and that it indemnifies the local authority against all proceedings. These are certainly weighty reasons in the case of a district which cannot well bear the cost of making experiments; as to the most efficient process available, and for its own sake we hope Hendon will, without further delay, decide on a matter which, to say the least, is fast becoming one of pressing im-

portance. Mr. Hancock also expresses the opinion that the "separate system" is best adapted to the requirements of the district, and he hence advocates the retention of the existing sewers for rain and storm waters, and the construction of smaller sewers than would otherwise be necessary for the conveyance of the sewage proper to its outfall.

#### THE LATE BARON CORVISART.

BARON LUCIEN CORVISART, whose death has just been announced, was formerly physician in ordinary to Emperor Napoleon the Third. Corvisart was parentage, and if related to his great name, physician to the First Napoleon, it was only in a distant manner. His medical studies were pursued at this time, during a popular disturbance he was fortunate to be slightly wounded by an insurrection together with his name, brought him into notoriety after he had obtained his degree of doctor he received an appointment in the imperial household and eventually became physician in ordinary to the Emperor, a post which he held until the death of Napoleon. Since then he has resided partly in England and partly in France. During the crisis which followed the famous decision of the Seize Mai, he presided over the unsuccessful candidature for Parliament, at a time he has not appeared in any public character, during a flying visit to Paris that he died a few weeks, at his house in the Champs Elysées. His work was principally connected with the therapeutics of pepsine, for his researches upon which he obtained the Corvisart, in his capacity of physician to the Emperor, present at the consultation which took place at the Hôtel de Clugny, Ricord, Germain Sée, and Couneau, agreed, chiefly at the instance of Professor Germain Sée, that there was reason to explore the genito-urinary passages of their august patient. This was shortly before the Franco-Prussian War. For political reasons the result of their deliberations was not communicated to the Emperor; and there are many who think that this suppression changed the destinies of France. Had Napoleon known that he had a stone in the bladder, it is thought that he would not have been so ready to face a campaign. After the operation performed by Sir Henry Thompson on Napoleon the Third, Corvisart made some unpleasant strictures upon the treatment. Whatever may have been the feeling of the French at the time, it is now recognised that the Emperor's personal physician had no competence to criticise the line of treatment decided by the English physicians and carried out by Sir H. Thompson.

#### SUICIDE OF A CRIMINAL LUNATIC.

A FEW months ago at Montrose a butcher named White, while manifestly insane, murdered his wife and child, afterwards making an unsuccessful attempt at suicide. In due course he was placed in the lunatic wards of the Perth prison, and then on the 9th inst. succeeded in his self-murder. From the evidence at the inquest that White the week previous to the accomplishment of his purpose had shown marked suicidal tendency, he was placed in a separate room. Again admitted to the ward, he made another attempt and was then removed to a padded room with special supervision. Here he was left open so that, as the warder said, he might be watched, but he succeeded in darting past the warder and throwing himself over the balustrade of the ward, falling seven feet and a half and fracturing his neck. He was partly guarded by a suitable railing, but at the time it was open. Death occurred in fifteen minutes. A medical officer was not sent for till two hours after the accident. Upon this latter fact the sheriff very properly ani-

a special report by Professor Corfield, analyst to the Mayor, Hanover-square, Vestry, on the fines that have inflicted by the magistrates recently in cases of adulteration of food, in which convictions have been obtained on his certificates, he remarks: "I have on several occasions pointed out that the fines have appeared quite inadequate to the offences, and the tendency of the magistrates to inflict merely nominal fines seems to be increasing. However, that a man has been fined only 1s. and 7d. costs for adulterating milk with 20 per cent. of having previously been convicted of adulterating twice and fined 2s. 6d. and £1 3s. costs in each case, not to say proof been obtained that the fines imposed are not adequate, but the question is raised whether it is really while to put the machinery in work to get a conviction the only result is to bring the Act of Parliament into disrepute."

As a consequence of the Birmingham Corporation having decided to institute legal proceedings against several sanitary authorities in whose districts the river Tame is polluted, the Wednesbury Local Board have decided to ask the Parliamentary sanction to alter their present system of dealing with sewage. The new scheme is to embrace the whole of the district, and to carry it out will entail an expenditure of £1000.

At a recent weekly meeting of the Health Committee of the Liverpool Town Council, a proposition by Dr. Hamilton for the introduction of a system of notification of infectious diseases was carried. It was drawn up by a committee of medical men in Liverpool, and adopted by a meeting of the profession on January 10th, was lost by the casting vote of the chairman.

MR. J. I. IVEY, in Cornwall, appears to be a model temperance man. The Mayor, half the borough justices, and the majority of the Town Council are abstainers. The borough is pledged to support local option. In a population of 10,000 there is only one policeman, and last year there were only two convictions for drunkenness.

DR. CONWAY EVANS, having again urged upon the Strand Board of Guardians the want of a mortuary, has been once more met by the stereotyped official reply, "The matter is under consideration."

## VITAL STATISTICS.

### HEALTH OF ENGLISH TOWNS.

In twenty-eight of the largest English towns 5907 births and 4480 deaths were registered during the week ending the 23rd inst. The annual death-rate in these towns, which had been equal to 22·3, 23·4, and 26·9 in the three preceding weeks, further rose to 27·6 last week. The lowest death-rates in these towns last week were 20·0 in Derby, 21·1 in Leicester, and 21·3 in Portsmouth. The rates in the other towns ranged upwards to 31·3 in Manchester, 32·1 in Preston, 32·2 in Plymouth, 32·9 in Newcastle-upon-Tyne, 36·9 in Huddersfield, and 40·1 in Liverpool. The deaths referred to the principal zymotic diseases in the twenty-eight towns were 478, showing a decline from the numbers in the two previous weeks; 110 resulted from measles, 100 from scarlet fever, 106 from whooping-cough, 85 from "fever" (principally enteric), 47 from diarrhoea, 24 from diphtheria, and 6 from small-pox. The lowest death-rates from these principal zymotic diseases occurred last week in Oldham and Bristol; and the highest in Preston, Sunderland and Liverpool; measles caused the highest death-rate in Liverpool and Sunderland; scarlet fever in Leeds, Sheffield and Brighton; whooping-cough in Blackburn and Plymouth, and "fever" in Birkenhead, Derby, and Newcastle-upon-Tyne. The 24 deaths from diphtheria in the twenty-eight towns included 12 in London, 2 in Liverpool, and 2 in Halifax. Small-pox caused 4 deaths in London and its outer ring of suburban districts, 2 in Newcastle-upon-Tyne, and 1 in Wolverhampton. The number of small-pox patients in the metropolitan asylum hospitals, which had been 62 and 75 on the two preceding Saturdays, was 73 at the end of last week; 13 new cases of small-pox were admitted to these hospitals during the week, against 5 and 22 in the two previous weeks. The deaths referred to diseases of the respiratory organs in London, which had steadily increased in the six previous weeks from 330 to 637, were 633 last week, and exceeded the corrected weekly average by 61. The causes of 137 or 3·0 per cent. of the deaths in the twenty-eight towns last week were not certified either by a registered medical practitioner or by a coroner. All the causes of death were duly certified in Portsmouth, Leicester, Derby, and Cardiff; while the proportions of uncertified deaths were largest in Wolverhampton, Birkenhead, Oldham, Halifax, and Sunderland.

### HEALTH OF SCOTCH TOWNS.

The annual death-rate in the eight Scotch towns, which had been equal to 24·8, 28·0, and 32·1 per 1000 in the three preceding weeks, declined last week, under the influence of milder weather, to 30·8; this rate was, however, 3·2 above the mean rate last week in the twenty-eight English towns. The deaths referred to the principal zymotic diseases in these Scotch towns, which had been 128 and 116 in the two previous weeks, were 119 last week, and equal to an annual rate of 5·1 per 1000, showing a considerable excess upon the mean rate from the same diseases in the English towns. This zymotic rate showed the largest excess last week in Glasgow and Paisley. The fatal cases of whooping-cough in the eight towns, which had been 39 and 37 in the two previous weeks, rose to 43 last week, and included 28 in Glasgow and 7 in Dundee. The 23 deaths from scarlet fever corresponded with the number in the previous week, no fewer than 17 occurring in Glasgow. The 17 deaths attributed to diphtheria were within 2 of the number in the previous week; 11 were returned in Glasgow, 3 in Edinburgh and 2 in Dundee. Of the 11 fatal cases of measles, 9 occurred in Glasgow and 2 in Edinburgh. The 10 deaths referred to "fever," showed a further decline from recent weekly numbers; they included 4 in Paisley and 2 in Dundee. The deaths referred to acute diseases of the lungs in the eight towns, which had been 139, 185 and 231 in the three preceding weeks, were 228 last week, and exceeded by 86 the number from these diseases in the corresponding week of last year. The causes of 127, or 16 per cent., of the deaths registered in the eight towns last week were not certified.

## HEALTH OF DUBLIN.

The annual rate of mortality in Dublin, which had been equal to 24.9 and 33.6 per 1000 in the two preceding weeks, further rose last week to 38.1, and exceeded that recorded in any previous week of this year. During the first twelve weeks of the current quarter, the death-rate in the city averaged 26.2 per 1000, against 21.7 in London and 20.3 in Edinburgh. The 254 deaths in Dublin last week showed a further increase of 29 upon those in the two previous weeks, and included 19 which were referred to the principal zymotic diseases, and within one of the number in the previous week. These 19 deaths were equal to an annual rate of 2.8 per 1000 (against 2.9 and 2.2 from the same causes in London and Edinburgh), and included 6 from "fever," 6 from whooping-cough, 5 from diarrhoea, and 2 from diphtheria. The fatal cases both of "fever" and whooping-cough showed a decline from those returned in the previous week. The deaths both of infants and of elderly persons were more numerous than in any recent week.

## HEALTH MATTERS GENERALLY AT HOME AND ABROAD.

## HEALTH OF CALCUTTA.

We are in receipt of Surgeon-Major McLeod's report upon the health of Calcutta during the third, or summer, quarter of this year, which acquires additional interest from the threatenings of epidemic cholera which have from time to time been disclosed by the weekly returns reproduced by the Registrar General. The return of the health officer is somewhat remarkable, in these days of elaborate vital statistics, for stating merely the numbers of births, deaths, &c., without any reference to population or to rates calculated thereon. Fortunately for sanitary progress such an omission in health reports is rare, and in the interest of the health of Calcutta we venture to hope that the omission will not be a permanent one. It would appear, from the figures published by the Registrar-General, that the death-rate in Calcutta last quarter was equal to about 25.0 per 1000, differing but slightly from the rate in Bombay, and comparing favourably with that in Madras. We do not doubt, however, that the rate is far in excess of what it might be, and this fact can only be brought home to the conviction of those interested in the health of the city by the publication of death-rates for comparative purposes. The health officer reports that "the quarter has been, as usual, much healthier than either of the two preceding quarters of the year, but it ranks high in point of mortality among other third quarters." The deaths from "fevers" in the quarter were 802, and were considerably below the average for the season, a result attributed to "the even distribution of rain and the absence of dry intervals or breaks during which malarious fevers are apt to become more prevalent and to exhibit a severe type." The deaths from cholera were 144, and 14 above the average number in the two preceding quarters; in only three years of the decade were, however, higher numbers returned. The number in September showed a satisfactory decline. Only 4 fatal cases of small-pox were reported; and no information is given concerning the causes of 1454 of the 2727 deaths in the three months, which are classed under the heading "Other causes." More precise mortality statistics should be forthcoming for such a city as Calcutta, which has a population little short of half a million of persons.

## NEW COUNTY HOSPITAL AT AYR.

AFTER serving the wants of the town of Ayr for a period of forty years, the hospital there has been found insufficient for the increasing demands made upon it, and new buildings, which have been in course of erection for sixteen months, are now completed, and were opened for public inspection on Christmas Day. Hitherto the hospital has been of value chiefly to the people of the town, but recently the constitution was so altered that patients may be admitted from the country as well, and upon this basis the directors have made a successful appeal for subscriptions, the sum subscribed to the building fund being about £6900. Notwith-

standing very handsome assistance from many friends of the institution, who have together almost completed the furnishing of the various departments of the house, the amount already expended upon the building is £8589.

Consisting of a central block, with wings at either end, the building proper is in the French Renaissance style, and is built of red freestone. The central portion rises to a height of three storeys, and will form the administrative department of the hospital. Ornamentation has not been neglected, and the tower which adds to the appearance of the building is also utilised for purposes of ventilation. The dispensing and operating rooms are suitably arranged in the centre of the building, and well arranged and provided, the surgical instruments being supplied by Mr. J. H. Houldsworth. A well-passes the whole length of the main building, and wards in each wing. The nurses' room, kitchen, and waterclosets are placed in contiguity with the wards. On the ground floor there is a patients' recreation. The wards themselves and spacious, are heated by coils of piping, and while the ventilation is effected by means of ing to ventilators in the roof, and by the cook's sash-lifters attached to each window. floors in the wing devoted to the male wards containing eight beds, a smaller containing with two beds only. The same arrangement upstairs, except that the smallest of the rooms, furnished by Dr. Ronald, will be retained as a convalescents. On the female side the two wards arranged as on the male side, but one of the wards will be used as a waiting-room, while the other will be utilised as a children's ward. This last is named after Sir Andrew Walker, by whom it has been endowed to the extent of £500. At some distance from the main building the fever wards have been erected. These consist of two blocks of one storey each, detached. In each of these accommodation will be six male, four female, and two private patients. Each block is complete in itself, only one will be used during epidemics, while the arrangement will also allow of more complete separation of patients suffering from different fevers. In another detached building a disinfecting room, mortuary, post-mortem room, washing house, and laundry have been provided. The disinfection will be carried out in one of Dr. Ransome's chambers, in which, by means of gas, a temperature of 250° F. can be obtained without damage to the articles treated. A self-acting mechanism prevents any damage to the fabrics. It is intended to make this apparatus available for the disinfection of articles supplied by the public. The total number of beds will be 71, apportioned as follows:—For males, 26; for females, 16; for children, 4; for private patient, 1; for fever patients, 24. The drainage has been carried out on scientific principles, and altogether it may be said that the Ayr Hospital is fully equipped for the work upon which it will soon enter.

The handsome subscription list, and the great kindness prompting to the elegant fitting up of so many of the wards by different benefactors point to a healthy local interest, which along with an enthusiastic and skilful medical staff seem all that is needed for a prosperous and highly useful future. Dr. Charles C. Scott will be the first house-surgeon.

The new hospital buildings had a narrow escape from destruction by fire a few days ago. The hospital was being well heated in order to have it ready for the opening ceremony on Christmas day, and in this process the fire in one of the wards communicated in some way with work near it. It was discovered in time to be extinguished without much difficulty, and the damage done is

At Sheffield an inquest has been held of a pauper who had been poisoned by an overdose of laudanum. The deceased was an inmate of the hospital. Verbal instructions appear to have been given by the medical officer to the nurse to administer laudanum in some castor oil. An ounce of laudanum was sent up from the dispensary, and was placed in the deceased's bed. During the absence of the nurse the deceased drank the laudanum. The nurse was highly censurable.

THE salary of Dr. Maclean, medical superintendent of the Holborn Infirmary at Highgate, has been raised from £300 to £350 per annum.

"Andi alteram partem."

## DEATHS AFTER ABDOMINAL OPERATIONS FROM HEART-CLOT."

To the Editor of THE LANCET.

SIR,—In last week's LANCET Mr. Thornton is pleased to inform your readers that I would have improved my position whatever that may mean—had I stuck to pure Listerism in abdominal surgery. He shows in a table that his results head and tail are a fraction better than mine, his being 10·67, mine only 10·76. He omits altogether the not unimportant fact that he mixes up cases done twenty years when he was at school, and when everything had to be learned about the surgery of the abdomen with the results of the last few years, when the difficulties that attended the operations had mostly passed away. He may also be unaware of the fact that in my early cases are included all cases from incomplete operations. It is true that it is now long time since I published any of my results, for I am not of ovariotomy statistics, especially of that sort with which Mr. Thornton treats us, and I daresay your readers are aware. It is little to me whether my results are better or worse than those of others; it is much to me if I have a single death after an operation, except what may arise from an accidental or unforeseen cause. So far as my life Mr. Thornton is wrong. I think that the use of any spray used in long abdominal operations is a useless money and that it is sometimes a dangerous one. Before the use of "pure Listerism" the mortality attending my operations had gradually fallen. The results over fourteen years gave a mortality of 1 death in 7. Of the five years before Listerism, the mortality had fallen to 1 in 10½; of the last of these years, to 1 in 21; and taking the last 26 years, the mortality was, or at the rate of, 3·84 per cent. In 121 abdominal operations done with strict Listerism and with the utmost care, there were 8 deaths (6·61 per cent.). There was surely nothing gained by this; no improvement in position here. Then in two cases a spray of boro-glyceride was used, one of these being a very bad operation, where the ovarian tumours and uterus were so welded together that the whole uterus had to be removed. I then went back the old way, and did 45 cases without any spray and without any death. If to these we add 26 cases, with 1 death, done before beginning the spray at all, we have 71 operations without spray, and with only a single death, and a tumour removed was a malignant one. But to take a far better test. I have sent for the results of every operation done in the Royal Infirmary, extracted from the hospital books. These are in all 64:—

### Spray Cases.

	Cured.	Died.	Total.
Ovariotomy ... ..	18	3	21
Hysterectomy for fibroid ...	2	0	2
Batley ... ..	0	1	1

24 cases, with 4 deaths (16·66 per cent.)

### Boro-glyceride Spray.

	Cured.	Died.	Total.
Double ovariotomy with } hysterectomy ... ..	0	1	1
Hysterectomy for fibroid ...	1	0	1

2 cases, with 1 death.

### No Spray.

	Cured.	Died.	Total.
Ovariotomy ... ..	31	1	32
Hysterectomy for fibroids...	5	0	5
Batley for fibroid...	1	0	1

38 cases, with 1 death (2·56 per cent.)

It seems to me that these results have "reversed our respective positions," and that "pure Listerism" has treated my patients badly.

I will now tell Mr. Thornton how he may improve his position, as he calls it, or rather that of his patients. Let him, for once, put his pride in his pocket, and use a

drainage-tube in the very bad cases. He will have a very little more trouble for the first two days, and he may drain unnecessarily sometimes, but he may also bring down his mortality from 10·67 per cent. to the hospital results of 2·56 per cent. Surely this is something worth trying for; though even now, I dare say, nature may sometimes burst open the wound and drain for him.

In concluding his letter, Mr. Thornton thanks Mr. Tait "for the opportunity he has afforded him of demonstrating the superior results obtained by Listerism in ovariotomy and oöphorectomy." I also have to thank Mr. Thornton for the opportunity he has afforded me of demonstrating that the antiseptic principle may be safely carried out without using carbolic spray, or, as he calls it, "pure Listerism."

I owe an explanation to all the members of our profession for having taken no notice of an application made by one of their number for information. This is the first time that I have ever done so. I took no notice of Mr. Thornton's letter to me. He knows well the reason why I can have no communication with him. Has he altogether forgotten that little circumstance that happened two or three years ago? The apology that he long owes me has not yet come.

I am, Sir, yours obediently,

Edinburgh, Dec. 26th, 1882.

THOMAS KEITH.

### To the Editor of THE LANCET.

SIR,—I have just read Mr. Thornton's second letter, and as its purpose seems chiefly to show that he is a more successful operator than either Dr. Keith or myself, I am not disposed to follow him in an argument so profitless to your readers. I am writing away from home and therefore cannot say how much he wrongs Dr. Keith, but the figures he quotes for myself are entirely wrong. They should be 312 cases, with twenty-six deaths, giving a mortality of 8·4 per cent. But even if Mr. Thornton's figures were correct they prove nothing, and his line of argument is, for himself, a very dangerous one. If Listerism is so essential to success, and if with it he can get, even on his own showing, results only fractionally better than Dr. Keith and I get without it, there must be some truth in what Dr. Taylor said at Worcester, that "Listerism is only a cloak for bad surgery."

In the many discussions which have taken place on this point, Mr. Thornton persistently ignores the point which seems to me of the greatest importance of all, the use and disuse of the clamp.

In the present edition of my book I give these figures as the result of my practice:

	Cases.	Deaths.	Mort. per cent.
Clamp, non-Listerian ...	36	9	25
Clamp, Listerian ...	26	7	27
Ligature, non-Listerian ...	209	6	3
Ligature, Listerian ...	30	2	6·6
	301	24	8

It must be clear to every one that in a discussion of any of the numerous questions concerning ovariotomy, all statistics tainted with the murderous mortality of the clamp must be omitted. When this is done my own figures show nothing in favour of Listerism; and against Mr. Thornton's advocacy of it there is Mr. Wells' condemnation (which no private conversations with Mr. Thornton can qualify) and the fact that it has been given up by Keith, Bantock, Savage, and myself. Mr. Thornton tells me that I have never been able to grasp or understand Listerism. The statement is rash, but perhaps true; my only appeal is to be let alone about it, and not have it dragged in on every possible occasion. Every death, according to Mr. Thornton, is in the hands of an ovariotomist who does not use Listerism is due to septicæmia. Some day, perhaps, Mr. Thornton will tell us what his definition of septicæmia is, and what his own patients die of.

Only one other point deserves reply, and that is the history of the case which had been under Mr. Thornton at the Samaritan Hospital. She is a very intelligent woman and gave me a clear history, confirmed in its main features by her medical attendant. She was sent to the Samaritan Hospital to have a tumour removed and Mr. Thornton declined to remove it on account of the risk. It was then about two-thirds of the size which it had reached when I

removed it, and its weight after removal was thirty-three pounds. It was not a "small fibroid enlargement of the uterus," but a well-marked example of the soft oedematous myoma. If Mr. Thornton has yet to learn that this disease is not arrested at the menopause, then he can accept the other horn of the dilemma. If this had been an isolated instance of its kind I should not have made use of it, but I shall have an opportunity soon of entering further into this aspect of the question. I am, Sir, yours truly,

LAWSON TAIT.

#### ASSOCIATION OF FELLOWS OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

To the Editor of THE LANCET.

SIR,—Do we want an Association of Fellows of the Royal College of Surgeons of England to consider "all questions affecting the interest of the Fellows and the government of the college?" I personally am not prepared to give a definite answer one way or the other. On the one hand, we have a Council whom we elect ourselves, who do not hold office for an indefinite time, and with whose action we are for the most part, I suppose, pretty well content; moreover, it has been clearly shown, even in later years, that the Council can be influenced by a powerfully expressed representation from the Fellows. On the other hand, it is no doubt a pleasant idea to bind the Fellows together into a body corporate, if that were possible, even if but little practical outcome came of such a union; as indeed the experience of the Convocation of the University of London would seem to render not improbable. But granted, for the sake of argument, that such an association is advisable, I would protest against its being tacked on as a sort of appendage to the British Medical Association, to which it is in no degree germane. It is notorious that a considerable number of Fellows never attend the meetings of the Association, and that many would always be prevented from doing so owing to the time of year that its meetings are held. It is difficult to see how such an Association could possibly be representative; it is easy to understand how it might become cliquy, and therefore mischievous. If it is to be instituted, it would surely be better to hold it in London, and at the same time that the election of Councillors and the Fellows' dinner take place. Why should it not be held on the same day, or if that were impossible, on the day before or after the election?

I am, Sir, yours faithfully,

Dec. 20th, 1882.

RICKMAN J. GODLEE.

ON

#### EXAMINING THE SPUTUM IN LUNG DISEASES OR THE BACTERIA OF TUBERCLE AS A MEANS OF DIAGNOSIS AND PROGNOSIS, AND SOME REMARKS ON STAINING.

To the Editor of THE LANCET.

SIR,—I have lately used as a means of diagnosis of tubercle an examination of the sputum for tubercle bacilli in all my cases of lung disease where grounds for suspicion existed, and I have found such means of diagnosis very valuable, in many cases solving the question where auscultation gave merely negative evidence. In two cases of apparently chronic pneumonia the discovery of bacilli in the sputum of one and not in the other led to a decided diagnosis and a variation of treatment, which was afterwards completely established by the subsequent progress of the cases, for in the one decided symptoms of phthisis became established in one lung, and in the other the lung trouble completely cleared up; and if the theory concerning the existence and connexion between these bacilli and tubercle be correct we cannot too highly estimate the value of the means that the existence of these bacilli affords of forming a correct diagnosis and a consequent prognosis, which is so anxiously looked for by the friends in these cases. I have used the methods of Ehrlich and Heneage Gibbes, but find the latter's method the easier to follow, and at present use that solely. I prefer, however, that the secondary staining be done in methylene blue instead of chrysoidine; the surrounding

tissue is rendered more distinct, whilst the contrast between the red bacteria and the blue is greater than between the red and brown of the chrysoidine.

I regret to say that when I first used either method my attempts were failures for a long time, and I began to almost give up in despair when it occurred to me that at the time the methods were described the weather was very warm, and I discovered that the cover-glasses when in the magenta solution should be kept at a temperature of 100° F. This I found ensured a uniform and deep crimson stain to the bacilli, so that in the sputa, examined previously without any result, I now found plenty of bacilli, and finding fresh sputa I found them at once. Typhoid putrefaction are not stained by this process, but which have passed through the nitric acid process washed, the putrefactive bacilli may be washed with a solution of gentian violet, with the tubercle bacilli—thus demonstrating the truth of proving that they are not identical. I find rapid work and purposes of diagnosis, the cover-glass after staining in methylene blue and washing with water, dried at once over a spirit-lamp flame, and solution of Canada balsam, in chloroform and examined at once. I have specimens prepared two months ago in which the bacilli can be easily seen by any one, even if not an experienced observer, may be clearly seen with a No. 6 Hartnack quarter-inch, and with the former the spherical ones are easily distinguished. I thus dispense with washing in absolute alcohol and drying in ether, also necessary that the washing after staining be done with distilled water. I find the dyes of Martindale are quite stable, and my preparations faded at all as far as I can judge.

I am, Sir, your obedient servant,

ENGLEDUE PRIDEAUX, L.R.C.P. I.

Wellington, Somerset, Dec. 1882.

#### THE DETECTION OF THE TUBERCLE BACILLUS.

To the Editor of THE LANCET.

SIR.—In your issue of last week you publish a long and somewhat incoherent letter from Dr. G. A. Heron, in which he impugns the veracity of my statements with regard to the new stain I have brought out for the bacillus of tubercle. Most of the objections raised in his letter were mentioned by him at the Medical Society's meeting, on the 4th of December, and refuted by me to the entire satisfaction, I think, of all present, saving of course Dr. Heron. He has, however, now done me the honour to review the various papers I have published on this subject, and to draw from them deductions not at all flattering to my truthfulness. I cannot allow these to pass without remark. Immediately after the meeting of the Medical Society, Dr. Heron appears to have called on Mr. Beck, the agent or salesman of the Badesche Anilin Fabrik, and he gives the result of his interview. On referring to the price list of this company I find that they do not quote fuchsin in it; what then could they do when a customer asked for fuchsin, but sell him the nearest thing they had to it? Does this, however, prove that fuchsin and magenta are the same? As to the use of these names on the Continent I can say nothing, but that they are used in the trade here to signify the same thing is not correct. Let Dr. Heron refer to the price lists of Messrs. Hopkins and Williams, Messrs. Son and Co., and Messrs. Becker and Co. He will find magenta and fuchsin both quoted, the one at double the price of the other. Does Dr. Heron think that firms of this standing are trying to defraud by selling the same substance under two names, charging in the one case double what they do in the other? Heron admits in his letter that he knows nothing of the chemistry of the anilin compounds. He is therefore unaware that magenta is a very comprehensive name, including the hydrochloride, acetate, nitrate and rosanilin. Does Dr. Heron think that all tubercle bacilli stain the same? If so I would advise him to make some original investigations into the subject, and then be able to speak with some authority on the matter.

The facts of the case are these: When Ehrlich

first published he mentioned fuchsin as the stain used, as well as methyl violet and gentian violet. By this stain I understood the fuchsin sold by Messrs. Hopkins Williams, and Messrs. Becker and Co., and which I used for a very long time for various staining purposes. I therefore made the stain by the method given, and tried I certainly could see the bacilli, which I never could do Koch's method. But they soon faded, which was exactly Dr. Heron's experience, *vide British Medical Journal*, 14th, p. 735, where he says: "These anilin dyes apt to fade very quickly; they may illustrate the presence of the tubercle bacilli at the examination of a prepared specimen, and within a few hours there may not be one of the organisms visible." On this I determined to try to find a better method, and for this purpose I made a very large number of experiments, and at last succeeded in making a stain which will not fade easily used—applying the anilin oil to make a definite pound and not for the sake of its alkalinity, as Ehrlich; using, also, a rosanilin salt and not fuchsin, which is, I believe, a by-product in the manufacture of rosanilin. Dr. Heron says in his letter last week, "I have repeatedly stained the bacillus under an ordinary  $\frac{1}{4}$  in. object glass, with very ordinary London daylight as my only illumination."

In his account of Ehrlich's method, published in the *British Medical Journal*, October 14th, page 735, he says, "power of 500 diameter is sufficient." If Dr. Heron is now using the same stain he did in August how does he account for this difference of opinion, that in August, he advised a  $\frac{1}{4}$  in. object-glass to "easily verify" that which he can now with a  $\frac{1}{4}$  in.? At the Worcester meeting he told me he could see the bacilli with a  $\frac{1}{4}$  in., but that he required special illumination. If the specimens he made then were easily shown why did he not exhibit some at the Worcester meeting? In his account of Ehrlich's process in the above-mentioned paper he states, "In the specimens prepared in this way before the section of pathology at Worcester, the bacilli were seen in large numbers." By whom were they seen? When I left the room everything was covered, and there were only a few people there, and from the time the section opened in the morning until I went away, Dr. Heron had not shown a single specimen under the microscope. I exhibited there two specimens of the bacilli in sputum under precisely similar conditions. One prepared by myself, the other after Ehrlich's method, and one of Dr. Koch's assistants. In mine the bacilli were very plain, in the other not one was to be seen. The power used was one of Messrs. R. and J. Beck's  $\frac{1}{4}$  in. economic series. The Ehrlich specimen they could be seen by artificial light. For the rows of bead-like bodies I would refer Dr. Heron to Mr. E. M. Nelson's drawing published in the *English Mechanic*.

In giving me a description of some preparations I sent them for examination, Mr. E. M. Nelson (who exhibited the specimens sent over by Dr. Koch to Mr. Cheyne at the various societies) says, "They are by far the finest specimens I have ever seen. The slide of sputum under a  $\frac{1}{4}$  in. N. A. 38 is a picture indeed. I could see the bacilli in that slide with a  $\frac{1}{4}$  in. eyepiece, with a  $\frac{1}{4}$  inch of 40° and A eyepiece they were readily seen. I could read them with a of 95°."

Dr. Heron admits that his specimens have faded; now mine have not, and those I showed at Worcester are as bright as ever, while two slides that were exposed to the daylight for over three months remain unaltered.

In conclusion, I would refer to the experience of the large number of men in this country, who after using Ehrlich's method are now using mine.

I am, Sir, very faithfully yours,

Gower-street, Dec. 25th, 1882.

HENEAGE GIBBS. 

## NEWCASTLE-ON-TYNE.

(From our own Correspondent.)

At the last meeting of the Hexham Rural Sanitary Authority the subject of coroners' certificates of death came before the board. Dr. MacLagan, medical officer of health, called attention in his report to the fact that 12½ per cent. of deaths were not registered by medical men, and the clerk said that coroners sometimes, without ascertaining the cause of death from a medical man, came to "some sort of

a conclusion themselves," and that in one case which came under his observation the jury found the person died from heart disease, without hearing the doctor who was waiting to give his evidence. After some discussion on this important matter, it was agreed by the board to send an extract from the medical officers report (Dr. MacLagan's) to the Local Government Board. It is obvious that in a great many cases a non-medical coroner must give certificates of the cause of death in cases of which he knows literally nothing; and it is to be hoped that this action of the Hexham board may lead to some good result at head quarters, or at least stimulate other boards over the country to ventilate the question of medical coroners, so long contended for by THE LANCET.

The Backhouse memorial wing of the Sunderland Infirmary has now been completed, and was formally opened on the 15th ult. For some time previous to 1879 it was felt that the additional accommodation was required at the infirmary, and the architect was instructed to prepare plans to meet the object in view. A new suite of bedrooms, kitchen, and other conveniences, were afterwards erected at a cost of £4000. Subsequently the work of erecting a new wing was vigorously pushed forward, and in May, 1881, the foundation-stone was laid. In consideration of the warm interest taken in the institution by the late Mr. Edward Backhouse, it was resolved to commemorate his acts of charity by designating the new erection "The Backhouse Memorial Wing." The new building is built on ground to the east of the institution, and its entire length is 185 feet, and its extreme width 52 feet. The new building contains a large, well-lighted hall, operating theatre, patients' wards, balconies, bath rooms, and lavatories, and is fitted with the latest scientific and sanitary improvements.

Considerable alarm is said to exist in Sunderland as to the present high rate of mortality, and the large amount of sickness existing in the borough and suburbs. The residents at the watering-place of Roker intend to ask the Government to send down an inspector to investigate the matter; but if the Roker people would insist on the thorough draining and cleansing of the main road leading to the place and its adjacent streets, it would in the meantime be a prudent procedure. It requires no Government inspector to see what is apparent to every visitor—namely, that the avenue approach to Roker is little better than a swamp, and with every facility afforded by Nature for natural drainage, it seems something like perverseness and a courting of disease to keep stagnant water before the doors of many of the most tasteful and well-built houses. Let the Sunderland people, especially those resident in Monkwearmouth and Roker, inspect their own streets and roads, using common sense, and the inspection will soon lead to a "new departure," sadly needed just now in sanitary work. They will thereby strengthen and encourage their own medical officer of health in the measures he has so strongly and plainly indicated, as necessary for the sanitary reform of the borough.

The last severe winter, which came to a close about a week ago, must be remembered as most destructive to life. Here in the northern counties, at least, nothing in the way of winter for the last twenty years could be at all compared to it, speaking as to effects; and for this purpose, disregarding the thermometer, old and young, weak and strong, at times succumbed to the chilling blast, and were suffocated in the snow on lonely roads and moorland downs. When the thaw came bodies were found here and there all over the country; even in the large towns the tramp, the waif, and I fear the drunkard, was found frozen to the ground. The death-rate may not show very much higher, but the amount of illness and deaths amongst the old has been very great.

I hear that a Bill is lodged in the House of Lords to empower a company to bring, "not coals," but sea-water, to Newcastle. Considering that anyone wishing for sea-water here may go down in a very few minutes and have it pure from the German Ocean (and as for sea-air, we have often more than enough of it when it blows from the north-east), we are naturally not very much interested in the success of this scheme; we do, however, require more facilities given for public bathing by baths and washhouses, and this could be better aided by good soft water.

In reference to the difficult abdominal operation of Mr. Jeaffreson, mentioned in my last letter, I hear that the patient still continues to do well, and may now be fairly considered out of danger.

## SCOTTISH NOTES.

(From our own Correspondent.)

ABOUT six years ago a number of benevolent people in Perth originated a home for incurables capable of accommodating some fifteen patients. Though the building was scarcely so suitable for its new purpose as could have been wished, the directors were able periodically to report a considerable amount of good work done. The increasing demands for shelter in the institution being luckily accompanied by a more robust subscription list, it was recently determined to acquire new and extended premises, and these have been secured at Hillside, in a suburb of the town. To the former dwelling-house wings have been added at each end, and as a consequence room will be provided for twenty-five additional beds. It is expected that the new home will be completed by March next. While on medical grounds the crowding of hopeless cases has obvious disadvantages, there will always be a sufficient number of these dependent creatures willing to embrace the advantages of a well ordered establishment of this kind. I believe the entire medical charge of the patients has hitherto been in the hands of Dr. Stirling, a warm friend of the institution, but a broadening of interest among the local profession might be suggested when the new buildings are opened.

The local authority of Kircaldy had the subject of hospital accommodation for infectious diseases recently brought under their notice by the Board of Supervision. It appears that in this increasing centre of trade there is at present no provision against an outbreak of fever, but steps are likely soon to be taken to remedy the defect, and a neighbouring proprietor has offered a suitable site for the new hospital. While welcoming such increased interest in sanitary matters, the question arises whether this is anything like adequate recognition of the needs of the locality in hospital accommodation, and if the present might not be a proper time for considering the subject on a broader basis. There is perhaps no county in Britain, certainly none in Scotland, with a larger industrial population so inadequately provided for in this respect. The coal fields of Fife furnish a large number of accidents yearly, and residents in that county do not need to be told how grievous have been the scenes in conveying many of these sufferers across the Firth of Forth to the Edinburgh Infirmary. It is almost certain that lives have in this way been sacrificed, and if a movement were originated for one large or two smaller general hospitals for the whole district, public spirit would not be wanting in support of the scheme. The hospital near Cupar is not even suitable for that town, and its situation prevents its use by residents in the seaboard towns and mining villages.

The amount and the causes of illegitimacy in Scotland are frequently commented upon, and thus it is satisfactory to know that a diminution, even though slight, appears during recent years to have set in. Mr. Seton, in a paper read before the Royal Society of Edinburgh a few days ago, was able to show that during the past twenty years the percentage of illegitimate births had fallen from 9.7 to 8.8 for the whole of Scotland. As England stands at 4.7 per cent. southern readers may think there is much room for further improvement with us, but I believe that a difference in the registration customs or laws has more to do with the matter than a more lax regard to the moral law on the part of the Scotch. Certain of our rural districts are, indeed, so conspicuously persistent in showing a high figure in these columns that the agricultural labourer must be branded as of most depraved character. The insular counties present the remarkable circumstance of a purely Scandinavian population with a low percentage of illegitimacy.

## BELFAST.

(From our own Correspondent.)

THE annual dinner of the Ulster Medical Society was held in the Imperial Hotel, Belfast, on the evening of Thursday, December 7th. The chair was occupied by Dr. McKeown, Senator of the Royal University, who is President of the Society for the present session; and the vice-

chair by Dr. Cumming, Professor of Medicine, Queen's College, Belfast. There was a good attendance of the local medical men, and some representatives from other parts of the province of Ulster were present who had come to a general meeting of the North of Ireland Branch of the British Medical Association, held at the Royal Hospital on the same day. The usual toasts were given, and the speeches on the occasion were characterised by much good humour and cordiality.

At present considerable changes are taking place in the Belfast Medical School, which, it is hoped, will strengthen the very high position which it holds among the leading medical schools of Ireland. These changes have been occasioned principally by the fact that the University of Ireland (which has taken the Queen's) requires candidates for the medical degree "a certificate of having attended at a medical or infirmary hospital, where clinical instruction in diseases of women and children is given, for months, or of having attended for six months in a dispensary where similar clinical instruction is given." Further, the Senate recommends that students themselves of opportunities of attendance at hospitals for diseases of the eye, ear, and other special branches of medicine and surgery.

Some thought that, as we have in Belfast one of the best hospitals for diseases of women, two for diseases of the eye, and one for diseases of children, as well as a skin hospital, a plan would be to amalgamate the special teaching purposes, and to allow the students to attend at these institutions. However, at the annual meeting of the subscribers of the Royal Hospital, Belfast, in November, it was decided, after a very long and anxious discussion, to establish two new departments, one for diseases of the eye, and the other for diseases of the ear; and at the general committee and life governors, held Dec. 18th, Dr. Joseph Nelson was appointed Surgeon, and Dr. John W. Byers Physician for Diseases of Women. These gentlemen will probably soon enter on their duties.

The staff of the Royal Hospital is now larger than it has ever been before, and consists of four physicians, four surgeons, a physician for diseases of women, an ophthalmic surgeon, an assistant physician, an assistant surgeon, and a surgeon dentist. There is a large number of students at the Royal Hospital this year, and a good many of the advanced men are attending the Belfast Ophthalmic Hospital; while at the hospital for sick children, it is stated that there are thirty-seven students on the roll during the present session.

There is some falling off in the number of first year medical students at Queen's College this year owing to the circumstance that candidates for the M.B. of the Royal University have to pass what is termed the "First University Examination" before they enter, properly speaking, on their medical studies. As the subjects for this examination are non-professional, and can be made up by private study, and as students are not admitted to this examination until after the lapse of one academical year from their time of matriculation, it is clear that many of those men who would under the old régime have taken rank as first year medical students this session, are waiting out until they pass this examination before commencing their purely professional studies. The present session may, indeed, be regarded as a period of transition due to the changes inaugurated by the Royal University.

Some think that these requirements of the University will drive men back to other less severe boards; but there can be no doubt that those (and there is an ever increasing one) who wish to enjoy which a good university degree confers will not mind the additional time and trouble spent in preparation for examination. All lovers of education hope that the Royal University will adopt a very high standard for its medical examinations.

ADMIRALTY.—Fleet Surgeons David W. George Frederick Augustus Draw have been placed on the Retired List of their rank.—The following appointments have been made: Staff Surgeon Charles C. Goddard, to the *Curacoa*; Surgeon Archibald M'Kinlay, to the *Hector*; Surgeon Thomas Desmond Gimlette, to the *Hector*.

## NEW YORK.

— (From our Correspondent.)

An announcement is made that the German Government prohibited the importation of American pork at the of Germany. This once more revives the question as to the relative danger of using American hog meat, and as I have watched the subject on this side for some years, I offer your readers such facts as I have gathered. The policy of all interested in the exportation of pork to the United States is to deny that trichinæ exist in lean hogs; this statement is generally endorsed by the papers, and even to some extent by Government authorities. The many Chambers of Commerce throughout the country and those who deal in the article preserve a safe and inaction. Statistics therefore from such sources are not forthcoming, and the difficulty is great when an attempt is made to prove the truth of the various statements. The only reliable inspection of hog meat for trichinæ which has been made in the United States, was once made at Chicago under the auspices of the Board of Health by two microscopists. I believe about a thousand hogs were examined, the result being that 1 per cent. were found infected with trichinæ. Such a percentage certainly invited a closer consideration of the subject, but no steps were afterwards taken either to confirm or disprove the result of this single examination. Cases of trichinosis occur in the United States at rare intervals. The last case brought to my personal notice was of a family at Erie, Pa., where a family of five persons was attacked. The attending physician attributed the disease to typhoid fever, supposed to have been caused by a pig, but Dr. Ed. W. Germer, the health officer of the city, solved the mystery by finding trichinæ in pork of which all the persons had eaten. A portion of the psoas muscle was forwarded to me, and from sections made by myself I could display ten or twelve trichinæ in the field of the microscope at one time. The pig in question had been raised by the family, and it was clearly a case of trichinosis due to a native hog. Previously, another pig had been raised in the same sty; they had been fed with the same food, and reared under similar conditions. Both were killed at the same time, when one was found to be infested with trichinæ, while the other was entirely free from that parasite. A few weeks later, Dr. E. Wendt, of Hoboken, N. Y., reported the fatal termination of a case of trichinosis, attended by Dr. W. T. Kudlich, of the city. In this instance a robust young married couple was attacked by trichinosis, the case of the woman terminating fatally. Dr. Kudlich stated that the disease was unmistakably traced to home produce. On this occasion some interesting experiments and observations were made with the trichinæ found in the unfortunate man's body. None were found encapsulated, but a few had assumed the spiral form, or the preparatory stage, but the majority were free, and either stretched out or twisted at either extremity. Little pieces of the man's muscle were exposed to cold, and even frozen several times. After four days of such exposure the animation found them quiescent; but a gradual elevation of the temperature to 100° F. caused them to show active motion, and ten days later these parasites were still alive. Seven days after the death of the woman some of her muscle was allowed to undergo putrefaction, but the trichinæ still lived. On the day following the autopsy some of the fresh muscle was teased, and there being abundance of trichinæ many became isolated; these were never found to creep along in a definite direction, but some were seen to move in a manner to resemble the unfurling and recoiling of an eel, and a change of place was sometimes fortuitously effected. Dilute acids increased their motion, and alkalis had a contrary effect, while concentrated solutions of both rapidly killed them. In carbolic acid they squirmed and writhed before dying. Glycerine did not immediately kill them. A little fresh muscle was submitted to artificial digestion by being placed in a suitable fluid and exposed for twelve hours to about body heat. The muscle was in great part dissolved at the end of this time, and many free parasites were found in the liquid. They were, if anything, less active than they had been, and as the liquid cooled their movements ceased, but were renewed on re-heating the

slide. During this period of experimenting, a noteworthy fact of interest was observed, that the trichinæ had grown. Dr. Wendt on this occasion made the observation on the diagnostic value of examining small pieces of muscle from accessible regions in patients suspected of trichinosis. If the parasites were found, the evidence was of course incontrovertible; but he added, if *vice versa*, a conclusion could not be arrived at. In the present fatal case of trichinosis, small bits of the deceased woman's muscle were torn from the gastrocnemius and deltoid muscles; and while some specimens contained numerous parasites, others were found without them. In the diaphragm, intercostal muscle, and other well-known places of predilection, every examined specimen showed abundant parasites. In regard to the prevalence of trichinosis in the United States, medical statistics cannot be relied on; as Dr. Satterthwaite, President of the New York Pathological Society, observes, although a vast amount of labour has been expended on the origin, clinical history, and treatment of trichinosis, we have good reason to believe that it is seldom recognised during life, and even after death escapes notice, unless the examiner has his attention specially directed towards the possibility of its occurrence. Cases of trichinosis are certainly very often found in the dissecting-rooms and deadhouses. Dr. Carpenter's observation at the dead-house of the Bellevue Hospital has been that the encysted trichinæ are found more frequently in the pectoral muscles or the diaphragm than in the deltoids or the gastrocnemii. It is with the Germans only, who persist in eating raw ham, that trichinosis is found; others who thoroughly cook their meat appear to preserve immunity from contagion. I believe the result of the Chicago examination of pork showing a percentage of 8 per cent. of infected pigs to be perfectly unreliable as a test of the extent of the contagion among American hogs, and that if proper steps were taken to obtain trustworthy statistics a condition of American hogs could be shown which would inspire confidence for this staple article of food in foreign countries. I do not desire to discredit the work of the Chicago microscopists, but I maintain that a single test is valueless. What I desire to see is the result of daily examination carried over twelve months; with such statistics a sound average could be presented.

New York, December 2nd, 1882.

## Obituary.

C. MAC IVOR GOYDER, L.R.C.P., M.R.C.S.

OUR obituary, in reporting the death from typhus fever at Newcastle-on-Tyne, in his twenty-sixth year, on Dec. 16th, of Mr. Charles M. Goyder, surgeon, records the early close of a most promising and already distinguished career. Mr. Goyder was the only son of Dr. C. S. Goyder, of Spofforth, in Yorkshire, who died when his son was only nine months old. In 1874 Mr. Goyder gained the medical scholarship of the University of Durham, and then began his studies in the College of Medicine, Newcastle. He displayed at once not only great industry and application, but also talents of an unusually high order. He carried off the medal in all the principal classes, the Charlton scholarship for medicine, and the Dickinson scholarship for proficiency in all subjects, the latter being the highest honour obtainable by any student of the college; in fact, he came to the front at the first, and maintained his lead throughout his curriculum, far ahead of every student of his year. In 1878 he was selected junior house surgeon to the Newcastle Infirmary, but before he had held that office eighteen months he became a successful candidate for the post of senior house-surgeon in the General Infirmary at Sheffield. He held that appointment for about a year, but always longed to be back to his own hospital, and when the post of senior house-surgeon became vacant, in 1880, Mr. Goyder applied for it, and was held in such esteem by the medical staff and house committee that he was unanimously appointed. He brought to the discharge of his duties the same zeal and care which had always distinguished him, and his conduct in every respect was such as to gain him the esteem and regard of everyone, whether principals or subordinates. When he left the infirmary, scarcely a year ago, to take the practice of the late Dr. McLachlan, he was presented by the nurses with a handsome

timepiece and by the students with an illuminated address. He acted as hon. sec. at one of the sections in the late Sanitary Congress at Newcastle. Mr. Goyder was a man of singularly amiable disposition and highly honourable character, equalled only by his modest and unassuming manners. It is much to be feared that this promising young surgeon, in undertaking the work and responsibilities of a large general practice, overtaxed his physical powers, already perhaps weakened by a long residence in hospitals, and thus fell an easy prey to infection caught from attending his first case of typhus. He was carefully attended in his illness, which lasted just fourteen days, by his friends Drs. Arnison and Dixon, and was frequently visited by many of his numerous medical friends.

## Medical News.

**UNIVERSITY OF CAMBRIDGE.**—The following have passed the third examination for the M.B. degree:—

**FIRST CLASS.**—Brinton, B.A., Downing; Fuller, B.A., Gonville and Caius; Harrison, M.A., Clare; Richardson, M.A., King's; Sheild, Downing.

**SECOND CLASS.**—F. J. Allen, B.A., St. John's; Bullar, B.A., Trinity; Bullar, M.A., Trinity; Driver, M.A., Christ's; Hewitt, B.A., Christ's; Holthouse, M.A., Trinity; Newnham, M.A., Gonville and Caius; F. F. Schacht, Trinity; Swift, B.A., Gonville and Caius; Vos, B.A., Christ's.

**ROYAL COLLEGE OF SURGEONS IN IRELAND.**—At examinations held on the 11th inst. and following days, the undermentioned candidates obtained the diploma in Surgery of the College:—

Arthur Cottew, Michael Cleary, Thos. B. Clune, Walter W. S. Corry, John Craig, Francis J. Cruise, Cornelius Daly, Michael O'F. Dolphin, Percy J. Drought, James E. Fitzgibbon, John W. Gormley, Francis B. Hawes, George B. Haffernan, David W. Kennedy, Richard T. King, Thomas Lane, Edward E. Lennon, John J. Lyons, Hercules S. Miles, Hy. J. O'Brien, Denis M. O'Callaghan, John J. O'Hagan, Peter J. O'Reilly, Francis F. Peet, Francis E. Pim, Alfred E. W. Ramsbotham, George P. Ridley, James D. Ryan, George P. Torney, George A. Walpole, William H. Waterfield, Robert Wright.

**UNIVERSITY OF DUBLIN.**—The following degrees were conferred last week:—

**BACHELOR IN SURGERY.**—William Hallahan Bennett, Joseph Bulfin, William Alex. Carte, Francis Richard Cassidy, Arthur Wellington Fenton, John William Gowland, George Marshall Lloyd-Apjohn, Francis Albert de Thierry Monillot, Henry William Peard, Angus Mayberry Whitestone.

**BACHELOR IN MEDICINE.**—John Armstrong, Francis Richard Cassidy, Eugene Cormack, Richard Geo. Hanley, Arthur Wellington Fenton, John Fitzgerald, Dionysius William Freeman.

**MASTER IN SURGERY.**—Charles Gorman.

**DOCTOR IN MEDICINE.**—Charles Gorman, Edward Gordon Hull.

**LICENTIATE IN MEDICINE.**—Joseph Patrick Finegan.

**LICENTIATE IN SURGERY.**—Joseph Patrick Finegan.

**APOTHECARIES' HALL.**—The following gentlemen passed the examination in the Science and Practice of Medicine, and received certificates to practise, on Dec. 21st:—

Cuffe, Robt. Ernest Gilhurst, Woodhall Spa Villa, Lincolnshire.

Davidson, Hugh Morgan, Aldeburgh, Suffolk.

Dent, Harry Lord Richards, Wood-street, Woolwich.

Griffin, Richard Palk, Padstow, Cornwall.

Lyons, Thomas, Brompton-road.

Wingrave, Vitruvius Harold W., Torrington-square.

The following gentlemen also on the same day passed the Primary Professional Examination:—

Robert Holloway, St. Thomas's Hospital; James Howard Clarke, Charing-cross Hospital; Wm. Thos. Rees and William A. Wetwan, London Hospital; Wm. Stanley N. Shorthouse, Guy's Hospital.

THE Queen has presented six birch lounge chairs, provided with shifting backs and soft crimson covered cushions, to Netley Hospital, for the use of the invalids in that establishment.

IN answer to a special appeal by the President of the Weston-super-Mare Hospital for funds to extinguish the debt of £380 existing on the institution, the sum of £300 has been collected or promised.

**MANCHESTER ROYAL INFIRMARY NURSES' HOME.**—Some time ago a special subscription was set on foot for the provision of more comfortable quarters for the nurses of this

infirmary. The effort resulted in the collection of nearly £6000 for the purpose. With this sum a substantial building has been erected at the rear of the Portland-street wing of the hospital, and was last week occupied by its full complement of inmates. Accommodation has been provided for the lady superintendent, the home sister, and seventy-seven nurses, each having a separate bedroom.

THE ball recently held at West Hartlepool in aid of the Hartlepool Hospital was financially a success, being fully equal to expectations. The gross proceeds amounted to fifty guineas.

**REQUESTS TO IRISH HOSPITALS.**—Miss Sarah Peter, £100 to Adelaide Hospital; Mr. R. M'Quiston, £100, and Mr. Robert M'Geah, £100, to the Belfast Royal Hospital. The Board of Stearne's Charity, £60 to St. Mark's Ophthalmic Hospital, Dublin.

OVERWORK of the railway officials seems likely to have been the chief cause of the collision at Cowlairs Junction in Scotland on the 16th inst. The men in charge of one of the trains had been on duty for seventeen hours and a half, those of the other for nearly seventeen hours. Some means must be found of ensuring that good dividends are not made at the expense of public safety.

THE body of Captain Lopes, who died from typhoid fever in Egypt, was brought home in the *Lusitania* transport, which arrived at Portsmouth on Wednesday with reserve men and invalids, upwards of 900 in number, inclusive of a few officers. No deaths occurred during the voyage. The late officer's brother arrived to take charge of the remains, which were taken to Melksham, Wilts, for interment.

**ROYAL MEDICAL BENEVOLENT COLLEGE.**—The general meeting of governors which was summoned for Wednesday, Dec. 20th, for the purpose of making certain alterations in the by-laws affecting the school, failed for want of the attendance of a sufficient number of governors to form a legal quorum. Much disappointment was expressed by those present at the want of interest in the important business to be transacted, shown by the paucity of attendance. Eventually the meeting was adjourned to Wednesday Jan. 10th, at 4 o'clock.

**SOUTH LONDON SCHOOL OF PHARMACY.**—The following are the successful competitors at the examinations held last week at this school:—Senior Chemistry: no prize awarded. Junior Chemistry: Mr. Parker (medal), and Mr. Oldershaw (certificate). Botany: Messrs. Pridmore (medal) and Harvey (certificate). Materia Medica: Messrs. Armstrong (medal) and Oldershaw (certificate). Pharmacy: Messrs. Oldershaw (medal) and Johnson (certificate). Extra certificates were gained by Messrs. Burton, Horsefield, Hurcombe, Austin, Arnott, and W. Kinson.

## Medical Appointments.

Intimations for this column must be sent DIRECT to the Office of THE LANCET before 9 o'clock on Thursday Morning at the latest.

BENNETT, REGINALD HENRY KEMP, L.R.C.S.I., has been appointed Surgeon to the Grenfell Hospital, New South Wales.

BRUCE-CLARKE, M.A., M.B.Oxon., F.R.C.S., has been appointed Surgeon to the Out-patient Department of St. Peter's Hospital for Stone.

EVANS, THOMAS, M.R.C.S., L.S.A.Lond., has been appointed Hon. Consulting Surgeon to the Randwick Asylum for Destitute Children, Sydney.

FENWICK, E. HURRY, F.R.C.S., has been appointed Surgical Registrar to the London Hospital.

FITZGERALD, WILLIAM A., M.B., has been appointed Clinical Assistant to St. Mark's Ophthalmic Hospital, Dublin.

GREAVES, HENRY, L.S.A.Lond., has been reappointed Medical Officer of Health for the Ashbourn Urban Sanitary District.

HOPKINS, H. CULLIFORD, M.R.C.S., has been appointed Public Vaccinator to the City and Borough of Bath, vice G. E. Lawrence, deceased.

HORSFALL, THOMAS, M.R.C.S., L.S.A.Lond., has been appointed Resident Medical Officer to the Leeds Public Dispensary, vice Hurtle, resigned.

HURST, GEORGE, M.B., C.M.Edin., has been appointed Honorary Consulting Physician to the Randwick Asylum for Destitute Children, Sydney.

W. HUGH, L.R.C.P.Ed., M.R.C.S., has been appointed Resident Medical Officer to the Leeds Public Dispensary, vice Oates.  
 J. T. M.B., C.M.Ed., has been appointed District Surgeon the Inanda Division of the County of Victoria, Natal, South ca.  
 E. ROBERT, M.D.Lond., has been appointed Pathological Lecturer to the Manchester Royal Infirmary, vice A. H. Young, Edin., F.R.C.S., resigned.  
 RICHARD T., M.R.C.S., L.R.C.P., has been appointed Public Sanitarian for the Darlington District of the Darlington Union.  
 ST. GEORGE, M.R.C.S., has been appointed Medical Officer the Sixth District and the Workhouse of the Launceston Union, Pearce, resigned.  
 ARTHUR QUARRY, M.D., B.S.Lond., M.R.C.S., has been appointed Pathologist and Curator to St. Mary's Hospital, vice person, resigned.  
 WILLIAM BEATTIE, F.R.C.S., L.R.C.P.Ed., has been appointed Deputy Medical Superintendent to the Yarra Bend Lunatic Asylum, Melbourne.  
 EDW. TULL, M.R.C.S., L.S.A.Lond., has been appointed Assistant Clinical Assistant and Registrar to the North-Eastern Hospital for Children, vice West.  
 T. H., L.R.C.P.Lond., M.R.C.S., has been appointed Resident Medical Officer to the City of London Hospital for Diseases of the St. Victoria-park, vice L. Humphry, M.B., resigned.  
 JOHN ARTHUR, M.R.C.S., has been appointed House-Surgeon the North-Eastern Hospital for Children, vice Dalton, whose appointment has expired.  
 HENRY, M.B., M.R.C.S., has been appointed Surgeon to the Leith District of the London Steamboat Provident Society.  
 ALFRED HARRY, F.R.C.S.Eng., M.B.Edin., has been appointed Medical and Surgical Registrar to the Manchester Royal Infirmary.

## Births, Marriages, and Deaths.

### BIRTHS.

R.—On the 9th ult., at Moonta, South Australia, the wife of Kendray Archer, of a son.  
 T.—On the 20th inst., at Camberwell New-road, the wife of Alfred Arnott, L.R.C.P.L., of a daughter.  
 ROSS.—On the 21st inst., at Shian Lodge, Penzance, the wife of Joseph Carne-Ross, M.D., F.R.C.P.Ed., late Lieut. 73rd Regiment, of a son.  
 FLOTT.—On the 22nd inst., at Sandgate, Shorncliffe Camp, the wife Surgeon-Major W. Floftott, Army Medical Department, of a daughter.  
 WALD.—On the 21st inst., at The Green, Southall, Middlesex, the wife of George Bruce McDonald, M.D., of a son.  
 E.—On the 21st inst., at Knighton, Anglesey, near Gosport, the wife of Dr. Warren Meade, of a son.  
 F.—On the 20th inst., at Steyne, Worthing, the wife of Frank Fish, M.R.C.S., L.R.C.P., of a daughter.  
 —On the 13th inst., at 24, White Horse-lane, Stepney, the wife Henry Reeve, Esq., of a son.  
 E.—On the 24th inst., at The Crescent, Kingsland, the wife of Alexander Towne, M.R.C.S., L.S.A.Lond., of a daughter.  
 E.—On the 26th inst., at Kirkmead, Woodford, Essex, the wife Frederick Turtle, M.D., of a son.

### MARRIAGES.

—VERDON.—On the 19th inst., at St. Mary's Church, Eastbourne, Surgeon-Major Oliver T. Duke, Beluchistan Political Agency, to the widow of the late Rev. H. B. Verdon, M.A., of Battersea, the youngest daughter of the late Henry Wheeler, Esq., of Lingbroke House, Wandsworth Common.  
 —COOKE.—On the 11th ult., at the British Episcopal Church, ante Video, Herbert Flower Parsons, M.R.C.S., L.S.A.Lond., of n Jorge, Durazno, to Katharine Elizabeth Nowell, daughter of a late J. Cooke, Esq., of Middridge Grange, Durham.  
 —BIRCH.—On the 11th ult., at Meerut, E.I., George Scott Robertson, I.M.S., Civil Surgeon, to Catherine Edith, daughter of out-Col. A. J. C. Birch, B.S.C.

### DEATHS.

—ON.—On the 21st inst., at Park Villas, Harpurhey, Sydney Henson, R.C.S., L.S.A.Lond., aged 55.  
 —EAN.—On the 19th inst., at the Royal Victoria Hospital, Netley, Surgeon-Major J. McK. MacLean, Army Medical Department.  
 —On the 26th inst., at Chichester, Richard Rugg, F.R.C.S.E., formerly of Brighton, in his 76th year.  
 —Drowned at Gypsey, Queensland, on the 16th October, Eric, the son and eldest child of Jessie Gertrude and John Pennefather, M.B., L.R.C.S.I., &c.  
 —R.—On the 21st inst., at his residence, Lapps Inland, Cork, William Kearns Tanner, M.D., F.R.C.S.I., aged 71.  
 —On the 2nd inst., at New York, John Phillips Payson White, D., aged 44.

B.—A fee of 5s. is charged for the insertion of Notices of Births, Marriages, and Deaths.

### BOOKS ETC. RECEIVED.

BLACKWOOD, W., & SONS, Edinburgh & London.  
 The Regulations of the Old Hospital of the Knights of St. John at Valetta. By the Rev. W. K. R. Bedford.  
 CHATTO & WINDUS, London.  
 Chapters on Evolution. By Andrew Wilson, Ph.D., F.R.S.E. Second Edition. pp. 382. With 259 Illustrations.  
 CHURCHILL, J. & A., London.  
 Notes on the Detection of the Acids usually met with in Analysis. For the use of Laboratory Students. By J. W. James, Ph.D. Jena. pp. 19.  
 The Relative Mortality after Amputations of large and small Hospitals, and the Influence of the Listerian System upon such Mortality. By Henry C. Burdett. pp. 41.  
 Nerve Vibration and Excitation as Agents in the Treatment of Functional Disorder and Organic Disease. By J. Mortimer Granville, M.D. pp. 128. With Illustrations.  
 Injuries of the Spine and Spinal Cord without apparent Mechanical Lesion, and Nervous Shock in their Surgical and Medical Aspects. By Herbert W. Page, M.A., M.C. Cantab. pp. 373.

## Medical Diary for the ensuing Week.

## Monday, Jan. 1.

ROYAL LONDON OPHTHALMIC HOSPITAL, MOORFIELDS.—Operations, 10½ a.m. each day, and at the same hour.  
 ROYAL WESTMINSTER OPHTHALMIC HOSPITAL.—Operations, 1½ p.m. each day, and at the same hour.  
 METROPOLITAN FREE HOSPITAL.—Operations, 2 p.m.  
 ROYAL ORTHOPEDIC HOSPITAL.—Operations, 2 p.m.  
 ST. MARK'S HOSPITAL.—Operations, 2 p.m.; on Tuesday, 9 a.m.

## Tuesday, Jan. 2.

GUY'S HOSPITAL.—Operations, 1½ p.m., and on Friday at the same hour.  
 WESTMINSTER HOSPITAL.—Operations, 2 p.m.  
 WEST LONDON HOSPITAL.—Operations, 3 p.m.  
 ROYAL INSTITUTION.—3 p.m. Professor Tyndall, "On Light and the Eye."  
 PATHOLOGICAL SOCIETY OF LONDON.—8.30 p.m. Annual General Meeting for Election of Officers.—The following specimens will be shown:—Arteritis at an Early Stage of Syphilis; Hepatic Cirrhosis in a Child; New Growths from Alimentary Canal; Chronic Inflammation of Glottis; Endocarditis with Disseminated Tubercle; Spina Bifida in a Child; Renal Abscess with Calculus (card specimen); Fibrinous Coagulum Loose in Left Auricle of the Heart; Fibrinous Coagulum Attached to Pleura; Lardaceous Disease of Liver; Polypl of Bladder in a Child; Animal Rickets; Crystalline Deposit in Hepatic Ducts of an Ox (card specimen).

## Wednesday, Jan. 3.

NATIONAL ORTHOPEDIC HOSPITAL.—Operations, 10 a.m.  
 MIDDLESEX HOSPITAL.—Operations, 1 p.m.  
 ST. BARTHOLOMEW'S HOSPITAL.—Operations, 1½ p.m., and on Saturday at the same hour.  
 ST. THOMAS'S HOSPITAL.—Operations, 1½ p.m., and on Saturday at the same hour.  
 ST. MARY'S HOSPITAL.—Operations, 1½ p.m.  
 LONDON HOSPITAL.—Operations, 2 p.m., and on Thursday and Saturday at the same hour.  
 GREAT NORTHERN HOSPITAL.—Operations, 2 p.m.  
 SAMARITAN FREE HOSPITAL FOR WOMEN AND CHILDREN.—Operations, 2½ p.m.  
 UNIVERSITY COLLEGE HOSPITAL.—Operations, 2 p.m., and on Saturday at the same hour.—Skin Department: 1.45 p.m., and on Saturday at 9.15 a.m.  
 EPIDEMIOLOGICAL SOCIETY OF LONDON.—7.15 p.m. Council Meeting.—8 p.m. Mr. Percival Gordon Smith, "On the Planning and Arrangement of Hospitals for Infectious Disease."

## Thursday, Jan. 4.

ST. GEORGE'S HOSPITAL.—Operations, 1 p.m.  
 ST. BARTHOLOMEW'S HOSPITAL.—1½ p.m. Surgical Consultations.  
 CHARING-CROSS HOSPITAL.—Operations, 2 p.m.  
 CENTRAL LONDON OPHTHALMIC HOSPITAL.—Operations, 2 p.m., and on Friday at the same hour.  
 HOSPITAL FOR WOMEN, SOHO-SQUARE.—Operations, 2 p.m., and on Monday at the same hour.  
 NORTH-WEST LONDON HOSPITAL.—Operations, 2½ p.m.  
 ROYAL INSTITUTION.—3 p.m. Professor Tyndall, "On Light and the Eye."  
 HARVEIAN SOCIETY.—Dr. Morton, "On a Successful Case of Ruptured Perineum."—Mr. Noble Smith, "On Lateral Curvature of the Spine (with specimens)."

## Friday, Jan. 5.

ST. GEORGE'S HOSPITAL.—Ophthalmic Operations, 1½ p.m.  
 ST. THOMAS'S HOSPITAL.—Ophthalmic Operations, 2 p.m.  
 ROYAL SOUTH LONDON OPHTHALMIC HOSPITAL.—Operations, 2 p.m.  
 KING'S COLLEGE HOSPITAL.—Operations, 2 p.m.

## Saturday, Jan. 6.

KING'S COLLEGE HOSPITAL.—Operations, 1 p.m.  
 ROYAL FREE HOSPITAL.—Operations, 2 p.m.  
 ROYAL INSTITUTION.—3 p.m. Professor Tyndall, "On Light and the Eye."

## Notes, Short Comments, and Answers to Correspondents.

It is especially requested that early intelligence of local events having a medical interest, or which it is desirable to bring under the notice of the profession, may be sent direct to this Office.

All communications relating to the editorial business of the journal must be addressed "To the Editor."

Lectures, original articles, and reports should be written on one side only of the paper.

Letters, whether intended for publication or private information, must be authenticated by the names and addresses of their writers, not necessarily for publication.

We cannot prescribe, or recommend practitioners.

Local papers containing reports or news-paragraphs should be marked.

Letters relating to the publication, sale, and advertising departments of THE LANCET to be addressed "To the Publisher."

## THE MELBOURNE MEDICAL SCHOOL.

CERTAIN changes have been, or are about to be, made in the medical curriculum at the University of Melbourne, which, according to the *Australian Medical Journal*, give promise of increasing its completeness and practical efficiency. A separate Professorship of Anatomy and Pathology is to be created, and distinct courses of pathological work are to be made compulsory. Steps also are being taken to place clinical medicine and surgery on a better basis, and it appears probable that special lecturers will be appointed in these subjects, as well as in pharmacy and therapeutics.

C. T.—A paroxysm of auditory vertigo is a functional disturbance, and no pathological changes in the nerve centres are known to attend it.

## THE TREATMENT OF CYSTIC BRONCHOCELE.

To the Editor of THE LANCET.

SIR,—In thanking "Chirurgus" for the light which his experience of cases of cystic bronchocele has enabled him to throw over my want of success in the Mackenzie method, followed by me in the case reported, I must again direct his attention to the author's description (*Clinical Transactions*, vol. vii., p. 116), wherein mention is made, not of the neutral salt, but "of a watery solution of perchloride of iron." If I am to conclude from his letter that my want of success was due to the presence of a free acid, &c., in the injection employed, my duty is manifestly to point out the inadequacy of the descriptions of the method, or of the use of iron in our standard works on surgery, which in the absence of the resources of the Clinical Society, and the published experience of "Chirurgus," are alone the guide of the country practitioner.

Erichsen (seventh edition, vol. ii., p. 410), in dealing with vascular and pulsating bronchoceles, says, "Injection of perchloride of iron is likely to be of service, but is not without the special danger of forming a plug, &c.," but no mention is made of a neutral salt. Gant (second edition, vol. ii., p. 384), in discussing the treatment of cystic bronchocele, says, "Injection of perchloride of iron has been found useful, subject to the risk of considerable inflammation, suppurative, and pyæmia." Or, again, Holmes (*Principles and Practice of Surgery*, third edition, p. 589), in quoting Mackenzie, simply mentions "a solution of perchloride of iron."

Judging from the use of perchloride of iron in cases of post-partum hæmorrhage, it would seem that, although not free from danger, the presence of a free acid in an alcoholic solution (even of quadruple strength) is not altogether guilty of the evils imputed to it as a therapeutic agent in another condition (I allow in the former for a relaxed and open orifice), and I have yet to learn that the severity of the inflammatory process set up by the alcoholic solution in the case in point would have been materially lessened by the use of the neutral salt.

Concerning the drainage, up to the fifth day the exit for the amount of discharge from the contracting coagulum at the orifice of the wound, in the absence of normal suppuration, was sufficiently provided for; indeed, to further that end, the cannula was temporarily, the plug permanently, removed before the date prescribed by the author of the method. Owing, however, to the activity of the suppurative process (now established, fifth day) a free incision into the cyst was suggested, but the condition of the patient and the remonstrance of the friends at this date forbade further surgical interference. And this prompts me to remark that the dictates of duty, no matter how strong, in country practice are rendered subservient, and therefore secondary, to public sentiment by virtue of reason being but the tardy handmaid of a people full of superstition and prejudice, and to depart from the too commonly pursued policy of "temporising" is but to shake rather than to inspire the public confidence; hence the second aspiration.

I am, Sir, yours faithfully,

December 4th, 1882.

H. A. SMITH.

P.S.—I might mention that free drainage is not hinted at in Dr. Mackenzie's paper even as a contingency.

—The Roll of the College of Physicians, by Dr. W. Munk, may be the desired information. Only one name occurs to us amongst ians, that of Dr. William Stroud, who died in 1858, who devoted of his time to biblical pursuits, and was the author of a Treatise on Physical Cause of the Death of Christ, &c., and a Harmony of our Gospels. Amongst surgeons may be mentioned the late Mr. South, who, it is not generally known, was the author of "The Catechism with Scripture Proofs," by a Layman.

#### PHYSICIANS' PRESCRIPTIONS.

To the Editor of THE LANCET.

—Would you be good enough to give me your opinion on the following question:—

six months ago my doctor gave me a prescription, which he told me only be made up at a certain chemist's. I had the medicine made up, and with an excellent effect. Being cured, my doctor sent me a bill—£15 for thirty visits—and I at once sent him a cheque. This being in need of the same medicine, I take the old prescription to the chemist's, and ask them to make it up. This they refuse to do on the ground that my doctor had forbidden them to dispense it without a prescription. I apply to my doctor, and he writes me that those are his terms to the chemist, and that each time I require that medicine I can obtain it by first applying to him for an order. I do not care to be so childishly. Would you inform me if a chemist has a right to refuse to make up a prescription he has already dispensed, and also if a doctor has the right to order a chemist not to dispense any other prescription of his? I paid my doctor 10s. for that prescription, and contend that it is my property, not his; and that I am free to have it made up every day if I choose. What do you say?

I am, Sir, yours, &c.,

INQUIRER.

Number 21st, 1882.

A medical man is at liberty to make his own terms as to attendance, the system described in our correspondent's letter is not generally followed or approved. A medical man either dispenses or prescribes. If he prescribes, the prescription ought to be the property of the patient, to be used when and how he pleases, and ought to be written in such a way that it may be compounded by any legally qualified chemist.—ED. L.

—"The Blane Medal" is awarded to medical officers in the Royal Army only. Mr. Robert McCormick, F.R.C.S. Eng., who took charge of an expedition up Wellington Channel in search of Sir John Franklin, is living at Wimbledon, and is upwards of eighty years of age.

#### CINCHONA BARK.

To the Editor of THE LANCET.

—I shall be glad if you could, through your influential journal, bring the growers of cinchona bark in bringing their valuable tonic to the reach of the million at a price which will well content the consumer, and not be exorbitant to the labouring poor.

The importance of this new branch of Indian and Ceylon industry is remarkable, and their fine cinchonas, rich in sulphate of quinine, are the corky barks of South America before them. But, although the price obtained in London at wholesale auctions does allow a splendid profit to the manufacturer who converts the bark into sulphate of quinine, yet a further immense profit is made by the retail chemist, who purchases it at 7s. or 8s. per ounce of 437 grains, and retails it at 30s. per ounce, profit on 480 grains to the ounce. And this magnificent tonic, valued by physicians on account of the certainty of its effects, cannot be prescribed by doctors in the quantities they would wish to a poor man or his wife and children, owing to the exorbitant rates charged by retail chemists (especially country chemists) in making up a prescription, so that practically it is only the moderately wealthy to whom the doctor's quinine prescription without stint.

One of the largest cities of the north I lately purchased a packet of cinchona powder, being charged 1s. 9d. for thirty-six grains, or at the rate of 23s. per ounce; and the druggist seemed surprised at my remarks on the price. If this is the price at our town establishments, what must be the price in country towns and villages? And in the interest of the masses of the people and the hard-working planter I would solicit your aid.

I am, Sir, yours faithfully,

THOMAS DICKSON, Managing Director.

The Scottish Trust and Loan Company of Ceylon (Limited),  
Palmerston-buildings, London, Dec. 21st, 1882.

A letter of Dr. Struthers on Scotch qualifications, as well as several other communications, are unavoidably held over till next week.

Quirer.—Yes.

#### ACTION OF CERTAIN DRUGS DURING PREGNANCY.

To the Editor of THE LANCET.

SIR,—Would any of the readers of THE LANCET give me the benefit of their experience in the following case:—

An anæmic patient of mine, who is subject to severe attacks of cramps which nothing will relieve except the administration of arsenic and iron in combination, is now pregnant. Would the first-mentioned drug be likely to have an ill effect upon the child, and would there be any fear of the iron bringing on abortion?

I am, Sir, yours faithfully,

December 26th, 1882.

INQUIRERS.

D. W.—Southey, the poet, and Sir Walter Scott had a very high opinion of the late Dr. Robert Gooch, who was born at Great Yarmouth, the birthplace also of Sir James Paget. Dr. Gooch's second wife was a sister of Mr. Benjamin Travers, President of the College of Surgeons, not his daughter. Dr. Gooch was the first medical man appointed Librarian to the Sovereign. The late Mr. Pettigrew, surgeon to Charing Cross Hospital, was Librarian to the Duke of Sussex.

Bibliophile.—There is a very good American medical biography in two volumes, 8vo, by Dr. James Thacher, containing several portraits; Hutchinson's Medical Biography; Pettigrew's Medical Portrait Gallery; Biographie Universelle; Dictionnaire de Biographie. Consult Mr. Chatto, Librarian of the College of Surgeons, or Mr. Wheatley, of the Royal Medical and Chirurgical Society.

#### THE MEDICAL PROFESSION AND LIFE ASSURANCE OFFICES.

To the Editor of THE LANCET.

SIR,—Many times I have been applied to by various insurance offices for my professional opinion upon the eligibility of the life of a proposer. I have invariably declined to reply unless my fee of one guinea was guaranteed. May I venture to suggest to you, as the Editor of our leading medical journal, that the offices which treat us honourably by paying for our skill should in justice to them be particularised in some way, as, for instance, by an asterisk being appended to the names of such offices; inasmuch as they honour us, we should honour them. A list in the index page of "General and Official Announcements" in THE LANCET, and a like notice in Messrs. Churchill's Directory would suffice. The presence of such asterisk would sufficiently indicate those offices to whom we could safely reply, knowing that we should be paid for our professional opinion.—I am, Sir, your obedient servant,

Kennington-park, December 19th, 1882.

GEORGE FOWLER.

\*. A similar suggestion to that contained in the above letter has been made before, but is difficult to carry out. Very few of the respectable assurance companies now, however, refuse a fee for a professional opinion, though the tariff varies considerably in different offices.—ED. L.

Depilatory.—Preparations known as depilatories simply destroy the hairs as they grow above the surface of the skin. To get rid of hairs permanently their roots must be destroyed, and to do this effectually without leaving scars, recourse must be had to operations varying in nature according to the site and character of the hair to be removed.

Mr. C. van Biema.—It could be procured through any instrument maker.

Dubitant.—Medical pass-lists are inserted when sent to us officially.

#### "SALICYLATE OF SODA IN SCARLATINA."

To the Editor of THE LANCET.

SIR,—Like Mr. Couldrey, I have tried salicylate of soda in persons suffering from scarlatina, and have fancied it did good. I have also given it to all persons in communication with the patient, and to those in the house unprotected by previous attacks, and have, as yet, always appeared to prevent the disease spreading. I have tried it thus, fifteen grains every four hours, in three different families, the first of which was the most striking example. It was in the family of a fishmonger, where the parents and four children slept in two adjoining rooms. One of the children was attacked by scarlatina, and in less than a week a second took it. There was no possibility of absolute isolation, but I put the other two children on comparative doses of salicylate of soda, whilst the parents took none, having previously had scarlatina. Both parents and one child had sore-throats for two or three days, but the other child never appeared to suffer in any way. This and other instances may be cases of *post hoc ergo propter hoc*, but made some impression upon the patients' friends, and may interest some of your readers.

I am, Sir, yours, &c.,

Upper Montagu-street, Montagu-square, W., AMAND ROUTH, M.D.  
Dec. 27th, 1882.

To the Editor of THE LANCET.

SIR,—A more extensive experience with the above has satisfied me that it is a very valuable medicine if used early and with sufficient power. It seems to modify the throat and nasal symptoms. The dose had better be left to the judgment of the practitioner. In my letter to THE LANCET of the 16th inst., "seven cases" should read "several cases."

I am, Sir, yours faithfully,

Scunthorpe, Brigg, Dec. 26th, 1882.

JAMES COULDREY.

A Member.—We believe the Museum of the College of Surgeons will be re-opened next month.

Mr. F. W. England.—May 20th and July 1st.

#### "APOMORPHIA IN CASES OF POISONING."

To the Editor of THE LANCET.

SIR,—I have just received a note from Dr. William Murrell, telling me that it was Dr. Gee who first introduced the use of apomorphia to the profession, and not himself, as I stated last week in your journal. You will oblige by kindly inserting this erratum.

I am, Sir, yours obediently,

Upper Montagu-street, Montagu-square, W., AMAND ROUTH, M.D.  
December 27th, 1882.

## BONE-SETTING.

We have received a communication on the above subject from a correspondent in Belper, who has not appended his name.

G. S.—The Catalogues of the Museum of the College of Surgeons have been compiled by several distinguished men, as Owen, Paget, Morris, Parkes, Taylor, Lowne, Stanley, Flower, Huxley, &c.

## HAMAMELIS VIRGINICA.—REMOVAL OF SUPERFLUOUS HAIRS.—PARASITE OF THE MOUSTACHE.

To the Editor of THE LANCET.

SIR,—Several recent communications in THE LANCET on the subjects above noticed induce me to send you the following.

*Hamamelis virginica* is an indigenous American shrub, growing chiefly in the New England States. It has been used by the laity as a domestic remedy in various complaints since very early times. It was first noticed in regular medicine by Dr. Fountain in 1848 (*New York Journal of Medicine*), and a year later by Dr. N. S. Davis (*Transactions of the American Medical Association*). It was recommended by these gentlemen as a remedy for hæmoptysis and hemorrhoids, taken internally for the former and used locally and internally for the latter. These notices fell dead, and for many years nothing further appeared on the subject except in the advertisements of a remedy known as "Pond's Extract of Witch Hazel." This preparation is not, pharmaceutically speaking, an extract. It is in reality a distilled water, obtained by distilling the bark of the young twigs with water and adding alcohol to the distillate to preserve it from decomposition. Since the introduction of this preparation numerous imitations of it have appeared, and I presume the hazeline of the English market is one of them. Your correspondent, Mr. Symes (THE LANCET, Nov. 4th) speaks of this as being "the active principle of the witch-hazel." This is unquestionably not the case. Thus far no active principle has been isolated. That *hamamelis* contains an active principle is undoubted, but thus far no one has been able to obtain it, although a great deal of time and money have been expended on the research. We simply know that it is not an alkaloid, glucoside, resin, or resinoid, but what it really is remains as yet a problem. The plant itself is of considerable commercial importance, and a good deal of capital is invested in the manipulation of it. One firm, for instance, manufacture a "concentrated extract," which they sell to dealers, who dilute it with alcohol and water and then place it on the market under various names. I presume hazeline is one of these, but cannot speak with certainty, as there is no preparation with this particular name on the American market.

*Hamamelis* is official in the new U.S. Pharmacopœia (1882), and official directions are given for the preparation of a "fluid extract." The writer has been familiar with the uses and virtues of *hamamelis* for many years, has made some fruitless chemical investigations as to the nature of its active principle, is one of the "Committee of Revision" of the Pharmacopœia, and believes that the official preparation is the one that will give the most satisfactory results in practice.

*The Removal of Superfluous Hair*.—In reply to "A Puzzled Practitioner" (THE LANCET, Nov. 4th) I would state that he will find the description of a successful procedure on page 307 of the writer's "Elementary Treatise on Diseases of the Skin" (Macmillan & Co., London and New York, 1876). The method described (electrolysis) has been used successfully by Michel Hardaway, Fox, and Heilmann in this country, and their observations have been recorded in the various journals of this country.

*Moustache Fungus*.—For the past three years a patient has presented himself during the month of July with a condition resembling that described by Dr. Thin in THE LANCET, Nov. 4th. Parasiticides have each time been sufficient to temporarily relieve the trouble and restore the hair.

I remain respectfully yours,

New York, Nov. 16th, 1882.

HENRY G. PIFFARD.

## "CLOAK ROOMS FOR LADIES."

To the Editor of THE LANCET.

SIR,—With your permission I should like to inform the writer of the letter which appeared in your journal of the 9th inst. with the above heading, that this company has been established to provide cloak rooms for both sexes in the public streets. As yet only one or two have been put up, as there is much difficulty in getting the local authorities in the metropolis and other large towns to give suitable sites. If the medical profession would only take the matter up as artily, and bring its influence to bear on the Vestries and Boards of Works, who have the power to grant sites, there is no doubt that such places would soon be as common in London as they are in the large continental cities. To show how much these cloak rooms are appreciated, I may mention that there are often over 100 women in the female compartment in the Whitechapel-road Châlet in a single day, while the number of men using the male compartment is above that.

I am, Sir, your obedient servant,

G. M. FORMAN, Secretary.

The "Châlet" Company (Limited), 17, Buckingham-street, Strand, W.C., Dec. 20th, 1882.

ERRATUM.—In Mr. Croude's note on Eczema last week, page 1105, for "liq. pot. brom." read "liq. pot. arsen."

COMMUNICATIONS not noticed in our present number will receive attention in our next.

COMMUNICATIONS, LETTERS, &c., have been received from—Sir Henry Thompson, London; Dr. Keith, Edinburgh; Dr. Broadbent, London; Mr. Van Biema; Mr. Cattley, Preston; Dr. E. N. Smith, London; Messrs. Mawson and Swan, Newcastle-on-Tyne; Dr. Lawrie, Lahore; Mr. Gant, London; Mr. Spearing, Shaw; Mr. Church, London; Mr. William Coates, London; Mr. Woodeson, Milton; Dr. Southery, London; Mr. T. #### MIRROR OF HOSPITAL PRACTICE, BRITISH AND FOREIGN.

BEDFORD GENERAL INFIRMARY.—A fish-hook in the oesophagus; extraction; recovery, 745

BLACKBURN AND EAST LANCASHIRE INFIRMARY.—Compound dislocation of astragalus forwards and inwards; excision, 441

BOOTLE BOROUGH HOSPITAL.—Severe injury to right foot; necrosis of metatarsal bones; operation; cure, 222

Bristol Royal Infirmary.—Severe case of stramonium poisoning; subcutaneous injection of morphia; recovery, 744

CHARING-CROSS HOSPITAL.—Rheumatoid arthritis treated by iodine and salicylate of quinine, 141—Tumour of bladder; digital exploration through median incision; removal of growth, 439

CUMBERLAND INFIRMARY, CARLISLE.—Chloroform faint in a case of ankylosis of elbow-joint, 629

DISTRICT HOSPITAL, WEST BROMWICH.—Rupture of liver; death in thirty-four hours, 449

ESSEX AND COLCHESTER HOSPITAL.—Ununited fracture of the olecranon; ends united by operation; cure, 843

GOSWELLS TUNIPAL HOSPITAL, BOMBAY.—Removal of elephantoid tumour of the scrotum, weighing 56lb., 142—Elephantiasis of scrotum, 223—Elephantiasis of scrotum; elephantiasis, of the labia vulvi; removal; recovery, 264

GREAT NORTHERN HOSPITAL.—Two cases of gunshot wound; remarks, 630

GREAT HOSPITAL, DUBLIN.—Lateral lithotomy; extraction of a large uric acid stone, 449

GUR'S HOSPITAL.—Cases of abdominal surgery, 101—Cases treated by hypodermic injection of pilocarpine, 221—Epithelioma occurring in an ulcer and in an old cicatrix, 359—Cancer of the rectum, 628—Acute abscess in lumbar region after injury; free opening; recovery, 619

HOSPITAL FOR CHILDREN AND WOMEN, WATERLOO ROAD.—Pyæmia with abscess and hæmorrhage into pleural cavity; necropsy, 318

KASHMIR MISSION HOSPITAL.—Compound fracture of both arms, 11—Two cases of hydatid of the liver, 441—Case of complete genital occlusion of the os uteri; operation; recovery, 669

LEDS PUBLIC DISPENSARY.—Aneurism of basilar artery; rupture; death; necropsy, 895

LIVERPOOL LOCK HOSPITAL.—Warty growths on the genitals, 630

LIVERPOOL NORTHERN HOSPITAL.—Extensive epithelioma of penis and scrotum; operation; satisfactory result, 10

LIVERPOOL ROYAL INFIRMARY.—Tuberculosis of urinary apparatus; death; necropsy; remarks, 188—Two cases where both breasts were removed for carcinoma, 1031

MANCHESTER WORKHOUSE HOSPITAL.—Abdominal aneurism rupturing into the psoas muscle, 314

MIDDLESEX HOSPITAL.—Cases of sarcoma, 6—Surgical cases, 702—Two cases of fracture of the skull in young patients, 816—Spontaneous rupture of the heart; survival for forty hours; autopsy; remarks, 939

NEWCASTLE INFIRMARY.—Eyelashes in the anterior chamber of the eye, the result of a stab, 493—Locomotor ataxia; nerve-stretching; no improvement, 671—Gastrostomy in a case of malignant stricture of the oesophagus, 1074

NORTHAMPTON GENERAL INFIRMARY.—Acute chorea complicated by pericarditis, endocarditis, cellulitis, &c., 847

NORTH STAFFORDSHIRE INFIRMARY.—Removal of entire uterus, left ovary, and Fallopian tube, 520—Case of pregnancy with retroversion of uterus, causing retention of urine (160 oz.); fatal result; remarks, 660

QUEEN'S HOSPITAL, BRISTOL.—Suicidal pistol wound of pericardium, heart, and stomach, 65—Subperiosteal resection of hip-joint for chronic hip-disease; cure, 222—Burn of abdomen, scrotum, and penis, causing phimosis; circumcision, 351—Spinal cancer; psoas abscess; incision with antiseptic dressing and a Sayre's case, 16

RADCLIFFE INFIRMARY, OXFORD.—Congenital hydronephrosis treated by aseptic incision in the loin and drainage, 141—Ununited fracture of the humerus in an old man successfully treated by resecting the ends of the bones, and fastening them together with a probe, 940

ROYAL DUCKS INFIRMARY.—Dislocation of the fifth cervical vertebra; reduction; recovery, 619

ST. ALBAN'S HOSPITAL.—Simple dislocation of the astragalus forwards and outwards; reduction, 352

ST. BARTHOLOMEW'S HOSPITAL.—Three cases of acute rheumatism complicated with pericarditis and pleuro-pneumonia; remarks, 283

ST. GEORGE'S HOSPITAL.—Sarcoma of the femur; amputation at the hip-joint; recovery; no return of the disease, 1073

ST. THOMAS'S HOSPITAL.—Some cases in which ovariotomy was performed, 63—Strangulated umbilical hernia, 185—Strangulated congenital hernia in a child twelve months old, 16—Traumatic neuroma of ulnar nerve, with loss of power of parts supplied, 457—Obstruction of the bowels; umbilical hernia; pregnancy; recovery, 570—Malignant disease of the pylorus; removal; death, 689—Popliteal aneurism cured by the use of Eschsch's bandage, followed by digital pressure, 1030—Injury to the head, in which recovery of consciousness was followed by relapse and death, 16

STAMEN'S HOSPITAL, GREENWICH.—Rupture of liver; thrombosis of hepatic veins; embolism of a branch of the left pulmonary artery; pleurisy; death; necropsy, 743—Transient right hemiplegia from injury to the head, 935

SHEFFIELD GENERAL INFIRMARY.—Case of ectropion successfully treated by transportation of a large non-pedicled flap from the arm, 102

SHEFFIELD PUBLIC HOSPITAL AND DISPENSARY.—Severe wound of the ankle-joint; recovery with movable joint, 599

STANLEY HOSPITAL, LIVERPOOL.—Ununited fractures of humerus, radius, and ulna successfully treated; remarks, 703

STROUD GENERAL HOSPITAL.—Ovariotomy during pregnancy; subsequent normal parturition, 965

SUSSEX COUNTY HOSPITAL.—Vesico-vaginal fistula; complete cure without an operation, 487—Cystic bronchocele cured by seton, 16

UNIVERSITY COLLEGE HOSPITAL.—Pylitis (tubercular?) without vesical disease; constant vesical pain removed by drainage of the bladder through a perineal aperture, 312—Two cases of increased eyeball tension; one reduced by eserine, the other by atropine, 504

VICTORIA HOSPITAL FOR CHILDREN.—Webbed arm, the result of scald; plastic operation, 44—Case of acute rheumatism, and one of ulcerative endocarditis, both simulating pyæmia, 155

WEST BROMWICH DISTRICT HOSPITAL.—Early perforation in typhoid, 744

WESTMINSTER HOSPITAL.—Ulcerative (peptic) endocarditis simulating enteric fever; death, 263

WOLVERHAMPTON AND SOUTH STAFFORDSHIRE HOSPITAL.—Excision of joint, 570

Missing link, a, pachysmia, 83

Mitral disease, the tonic treatment of, 938

stenosis in the gouty heart, 177

## REVIEWS AND NOTICES OF BOOKS.

- Clinical Lectures on Diseases of the Urinary Organs: by Sir Henry Thompson; sixth edition, 11—Handbook of Therapeutics: by Sidney Ringer, M.D., 12—On Concussion of the Spine, Nervous Shock, and other Obscure Injuries of the Nervous System in their Clinical and Medico-Legal Aspects: by John Eric Erichsen, F.R.S., 1b—Manual for the Physiological Laboratory: by Vincent Harris, M.D., and D'Arcy Power, M.A.; second edition, 1b—Household Chemistry for the Non-chemist: by Alfred Shillon, F.C.S., 1b—Catalogue of the Pathological Museum, Medical College, Calcutta: by J. F. P. McConnell, M.B., 54—De la Lithotritie Rapide: par Dr. Reliquet, 1b—Sarcoma and Carcinoma: by Henry Trentham Butlin, F.R.C.S., 1b—Hospital and their History, Construction, and Hygiene: by J. F. Sutherland, M.D. Edin., 106—On the Treatment of Cancer: by Professor John Clay, 108—Our Library Table, 1b, 442, 639, 897—Autiseptic Surgery: its Principles, Practice, History, and Results: by W. Watson Cheyne, M.B., F.R.C.S., 143—Manual of Diseases of the Skin, with an Analysis of 8000 Consecutive Cases and a Formulary: by L. D. Bulkley, A.M., M.D., 144—Experimental Physiology: its Benefits to Mankind: by R. Owen, C.B., M.D., F.R.S., 1b—The Surgery of the Rectum (Lectures on the Lectures on Surgery): by Henry Smith, F.R.C.S.; fifth edition, 1b—The Student's Guide to Diseases of the Eye: by E. Nettlehip; second edition, 145—Modern Dress and Clothing in its Relation to Health and Disease: by T. F. Pearse, M.D., 1b—Burdett's Official Intelligence, 1b—Physiologie des Muscles et des Nerfs: par Charles Richet, 1-7—The Journal of Anatomy and Physiology; Vol. XVI., Part IV., 1b—The Illustrated Quarterly Journal of Medicine and Surgery; Vol. I, No. 1 and II., 188—Manuel d'Hygiène Industrielle: par Dr. Henri Napias, 223—Lock Hospitals and Lock Wards in General Hospitals: by F. W. Loandres, M.R.C.S., 224—A Handbook on Diseases of the Skin: by R. Living, A.M., M.D. Cantab., F.R.C.P. Lond.; third edition, 1b—Archives Italiennes de Biologie; Vol. I., Parts I. and II., 1b—The Botanical Atlas: by D. M'Alpine, F.C.S.; Parts I. to III., 225—L'Année Médicale, 1881, 1b—Food, the r

- Composition and Analysis: by A. Wynter Blyth, M.R.C.S., F.C.S., 265—An Index of Comparative Therapeutics: by Samuel D. L. Potter, A.M., M.D.; second edition, 266—Nitro-Glycerin in Angina Pectoris: by William Murrell, M.D., M.R.C.P., 1b—Nouveau Dictionnaire de Médecine et de Chirurgie Pratiques; Tome XXXII., 314—Manual of Pathological Histology: by Coriil and Hanvier; second edition; Re-edited and enlarged; translated by A. M. Hart, 315—Human Parasites: by T. Spencer Cobbold, M.D., F.R.S., F.L.S., 441—The Pharmacology of the London Hospital, 442—The Surgery of Deformities: by E. Noble Smith, F.R.C.S.E., L.R.C.P. Lond., 1b—On the Climate and Fevers of India: by Sir J. Favre, K.C.S.I., F.R.S., 489—Spon's Encyclopedia of the Industrial Arts, &c.: edited by Charles G. Warford Lock, F.L.S., 4-9—Notes on Surgical Treatment and Minor Operations: by Thos. F. Hoggood, L.R.C.P., M.R.C.S., 490—Schematic Anatomy: by W. P. Mearns, M.B., 530—The Tissues and their Structure: by A. S. Kenny, M.R.C.S.E., 1b—The Compend of Anatomy: by John H. Roberts, A.M., M.D.; second edition, 1b—Publications of the Association for the Advancement of Medicine by Research, 1b—Die Parasitären Krankheiten des Menschen. I. Entwicklungs geschichte und Parasitismus der Menschlichen Crustoden: Von Sigmund Theodor Stein, 1b—Clinical Lectures on Diseases of the Nervous System: by Thos. Buzzard, M.D. Lond., F.R.C.P.; first notice, 571; Clinical Lectures on Diseases of the Nervous System: by Thos. Buzzard, M.D. Lond., F.R.C.P.; second notice, 620—Spontaneous Fever (Synonymus, Famine or Relapsing Fever), as seen in Western India: by H. Vandyke Carter, M.D. Lond., 698—Medical and Surgical Aspects of In Knee (Genu Valgum); its Relation to Rickets, its Prevention, and its Treatment with and without Surgical Operation: by W. J. Little, M.D., F.R.C.P.; assisted by K. Muirhead Little, M.R.C.S., 709—Health Resorts and their Uses: by I. Burney Yeo, M.D. Lond., 1b—Quarterly Journal of Microscopical Science, No. LXXXVIII., 709—Brain, Oct. 1882, 1b—The Diseases of the Spinal Cord: by Byron Bramwell, M.D., F.R.C.P. Edin., 746—Report of the Scientific Results of the Voyages of H.M.S. Challenger during the years 1873-76: prepared under the superintendence of the late Sir C. Wyville Thomson, and now of John Murray; Vol. II., 748, 1079—Therapeutical Remembrancer: by J. Mayne, M.D., L.R.C.S.E., L.S.A.; second edition, 1b—Clinical Lectures on Diseases of the Heart and Aorta: by Geo. Wm. Balfour, M.D.; second edition, 809—The Transactions of the Edinburgh Obstetrical Society; Vol. VI., 1b—Transactions of the American Gynecological Society; Vol. VI., 1b—Sitzungsberichte der Chirurgisch in Klinik des Herrn Professor Dr. Ritter von Nussbaum: Von Dr. Isenschneid, Erste Heft, 810—A Dictionary of Medicine, including General Pathology, General Therapeutics, Hygiene, and the Diseases Peculiar to Women and Children: edited by Richd. Quain, M.D., F.R.S. (First Notice), 854—A Practical Treatise on Electro-Diagnosis in Diseases of the Nervous System: by A. Hughes Bennett, M.D., 898—Chapters in the History of the Insane in the British Isles: by D. Hack Tuke, M.D., F.R.C.P., 945—Die Offentliche Reconvalenscentenpflege: Von Dr. Paul Gueterbock, 948—The Journal of Anatomy and Physiology; Vol. XVII., Part I., 1b—Quain's Elements of Anatomy: edited by Dr. Allan Thomson and Professors Schäfer and Thane; Ninth Edition, 957—The Student's Guide to Materia Medica and Therapeutics in accordance with the British Pharmacopoeia: by J. C. Thorowgood, M.D., F.R.C.P.; second edition, 1b—A Medical Formulary based on the United States and British Pharmacopoeias: by Lawrence Johnson, A.M., M.D., 1b—Catalogue of the Collections in the Museum of the Pharmaceutical Society of Great Britain: compiled by E. M. Holmes, F.L.S., 959—Diseases of Women: by Arthur W. Eds, M.D.; second edition, 1b—Ogilvie's Imperial Dictionary of the English Language: edited by Charles Annandale, M.A., 959—Animal Plagues, their History, Nature, and Prevention: by George Fleming, F.R.C.V.S., F.R.C.S., &c.; Vol. II., 1033—The Practical Working of Direct Vaccination from the Calf: by Benjamin Bowdoin, M.D., 1039—Nice and its Climate: by Dr. A. Baréty; translated, with additions, by Charles West, M.D.; and an Appendix on the Vegetation of the Riviera, by Professor Allman, F.R.S., 1080—Madeira: its Scenery, and how to see it: by Ellen M. Taylor, 1081—The Physicians' and Surgeons' Visiting List, Diary, Almanack, and Book of Engagements for 1883, 1081—Etudes de Physiologie Sociale: La Prostitution: par Yves Guyot, 1116—Municipal Sewage, and what to do with it: by Edward Mouson, A.M.I.C.E.; Part I., 1117—On Duty and a Tropical Sea:
